Proponents of social regulation point to its many specific benefits. Here are just a few examples: It is estimated that highway fatalities would be 40 percent greater annually in the absence of auto safety features mandated through regulation. Compliance with child safety-seat and seat-belt laws has significantly reduced the auto fatality rate for small children. The national air quality standards set by law have been reached in nearly all parts of the nation for sulfur dioxide, nitrogen dioxide, and lead. Moreover, recent studies clearly link cleaner air, other things equal, with increases in the values of homes. Affirmative action regulations have increased the labor demand for racial and ethnic minorities and females. The use of childproof lids has resulted in a 90 percent decline in child deaths caused by accidental swallowing of poisonous substances.

Some defenders of social regulation say there are many remaining areas in which greater regulation would generate net benefits to society. For instance, some call for greater regulation of the meat, poultry, and seafood industries to improve food safety. Others favor greater regulation of health care organizations and insurance companies to ensure “patients’ rights” for consumers of health care services. Still others say that more regulation is needed to ensure that violent movies, CDs, and video games are not marketed to children.

Advocates of social regulation say that the benefits of such regulation are well worth the considerable costs. The costs are simply the price we must pay to create a hospitable, sustainable, and just society.

Criticisms of Social Regulation Critics of social regulation contend that, in many instances, it has been expanded to the point where the marginal costs exceed the marginal benefits. In this view, society would achieve net benefits by cutting back on irritating social regulation. Critics say that many social regulation laws are poorly written, making regulatory objectives and standards difficult to understand. As a result, regulators pursue goals well beyond the original intent of the legislation. Businesses complain that regulators often press for additional increments of improvement, unmindful of costs.

Also, decisions must often be made and rules formed on the basis of inadequate information. Examples: CPSC officials may make decisions about certain ingredients in products on the basis of limited laboratory experiments that suggest that those ingredients might cause cancer. Or government

agencies may establish costly pollution standards to attack the global-warming problem without knowing for certain whether pollution is the main cause of the problem. These efforts, say critics, lead to excessive regulation of business.

Moreover, critics argue that social regulations produce many unintended and costly side effects. For instance, the federal gas mileage standard for automobiles has been blamed for an estimated 2,000 to 3,900 traffic deaths a year because auto manufacturers have reduced the weight of vehicles to meet the higher miles-per-gallon standards. Other things equal, drivers of lighter cars have a higher fatality rate than drivers of heavier vehicles.

Finally, opponents of social regulation say that the regulatory agencies may attract overzealous workers who are hostile toward the market system and “believe” too fervently in regulation. For example, some staff members of government agencies may see large corporations as “bad guys” who regularly cause pollution, provide inadequate safety for workers, deceive their customers, and generally abuse their power in the community. Such biases can lead to seemingly never-ending calls for still more regulation, rather than objective assessments of the costs and benefits of added regulation.

Two Reminders

The debate over the proper amount of social regulation will surely continue. By helping determine costs and benefits, economic analysis can lead to more informed discussions and to better decisions. In this regard, economic analysis provides pertinent reminders for both ardent supporters and ardent opponents of social regulation.

There Is No Free Lunch Fervent supporters of social regulation need to remember that “there is no free lunch.” Social regulation can produce higher prices, stifle innovation, and reduce competition.

Social regulation raises product prices in two ways. It does so directly because compliance costs normally get passed on to consumers, and it does so indirectly by reducing labor productivity. Resources invested in making workplaces accessible to disabled workers, for example, are not available for investment in new machinery designed to increase output per worker. Where the wage rate is fixed, a drop in labor productivity increases the marginal and average total costs of production. In effect, the supply curve for the product shifts leftward, causing the price of the product to rise.

Social regulation may have a negative impact on the rate of innovation. Technological advance may be stifled by, say, the fear that a new plant will not meet EPA guidelines or that a new medicine will require years of testing before being approved by the Food and Drug Administration (FDA).

Social regulation may weaken competition since it usually places a relatively greater burden on small firms than on

Antitrust Online

The Internet Has Presented Antitrust Authorities with Both Old and New Causes for Concern.

The Airline Tariff Publishing case was the first important example of how digital communication platforms could be used by businesses to engage in price-fixing. In the late 1980s, U.S. airlines began to post both current and future prices for airline tickets on a centralized computer system known as the Airline Tariff Publishing Company. The system was set up so that travel agents could comparison shop for their clients. But the airlines used the system's ability to list start dates and end dates for ticket purchases as a way of colluding.

As an example, suppose that American Airlines and Delta Airlines had both been charging \$200 for a one-way ticket between New York and Chicago. American could then post a higher price of \$250 for the route with the stipulation that nobody could start buying tickets at that price until the next month. Delta could then respond by also saying that it would start selling tickets at the higher price next month. In that way, the two airlines could tacitly coordinate their price setting ahead of time so as to collude on a major price increase.

The antitrust authorities at the U.S. Department of Justice stopped this practice in 1994 by getting the airlines to agree to the behavioral remedy that any fare changes would have to become immediately available to consumers. Airlines could no longer use suggested future prices as a way of signaling each other about how to collude.

The monopoly power gained during the 1990s and early 2000s by online giants such as Microsoft and Google has also led to business practices that have raised the ire of antitrust authorities. Microsoft, for example, was fined \$2.7 billion after being convicted in 2000 of using the near-monopoly (95 percent market share) dominance of its Windows operating system software to coerce computer makers into favoring Microsoft's Internet Explorer web browser over rival browsers such as Netscape Navigator.

More recently, Google was indicted in 2015 by European Union antitrust officials for allegedly using its 90 percent share of the market for Internet searches in Europe to favor its Google Shopping price-comparison service over price-comparison services run by rival firms. For example, if a person in Germany types "prices for used iPhones" into Google's search bar, the top of the search results page will feature images of several used iPhones for sale on Google Shopping. By contrast, anyone wanting comparison prices for used iPhones that are listed on other price-comparison sites will have to click on links further down on the search-results page to get to those other sites and their respective lists of used iPhone prices. Google faces up to €6.6 billion in fines if convicted.

© grzegorz knec/Alamy Stock Photo

The most recent threat to competition spawned by the Internet is the rise of collusion via pieces of software that use pricing algorithms (automatically applied rules for setting prices) to constantly adjust a company's the online prices in response to seeing what rival firms are charging for similar products. The problem for regulators is that the pricing algorithms of different firms could end up interacting in ways that collusively raise prices for consumers. This is especially true for pieces of software that use artificial intelligence to learn how to achieve preset goals. Two such pieces of software could each be programmed to try to maximize profits and, as they interacted with each other, "realize" that the best way to do so is by coordinating rather than competing.

That possibility is especially challenging because, given the way antitrust laws are currently written, firms can be prosecuted for collusion only if they make an anticompetitive "agreement" with each other. If the algorithms come to collude on their own, there is no such agreement to prosecute. In fact, the behavior of the two pieces of software could just as easily be interpreted as independent parallel conduct rather than coordination since they don't even directly communicate with each other. And, in addition, should asking a piece of software to try to figure out how to maximize profits be illegal just by itself?

These issues are still very much up in the air but being faced squarely by U.S. regulators, who made their first prosecution against the collusive use of algorithmic pricing software in 2015 and who established the Office of Technology Research and Investigation as part of the Federal Trade Commission's Bureau of Consumer Protection that same year.

large ones. The costs of complying with social regulation are, in effect, fixed costs. Because smaller firms produce less output over which to distribute those costs, their compliance costs per unit of output put them at a competitive disadvantage with their larger rivals. Social regulation is more likely to force smaller firms out of business, thus contributing to the increased concentration of industry.

Finally, social regulation may prompt some U.S. firms to move their operations to countries in which the rules are not as burdensome and therefore production costs are lower.

Less Government Is Not Always Better Than More

On the opposite side of the issue, opponents of social regulation need to remember that less government is not always better than more government. While the market system is a powerful engine for producing goods and services and generating income, it has certain flaws and can camouflage certain abuses. Through appropriate amounts of social regulation, government can clearly increase economic efficiency and thus society's well-being. Ironically, by "taking the rough edges off of capitalism," social regulation may be a strong pro-capitalism force. Properly conceived and executed, social regulation helps maintain political support for the market system. Such support could quickly wane should there be a

steady drumbeat of reports of unsafe workplaces, unsafe products, discriminatory hiring, choking pollution, deceived loan customers, and the like. Social regulation helps the market system deliver not only goods and services but also a "good society."

QUICK REVIEW 21.3

- ✓ Social regulation is concerned with the conditions under which goods and services are produced, the effects of production on society, and the physical characteristics of the goods themselves.
- ✓ Defenders of social regulation point to the benefits arising from policies that keep dangerous products from the marketplace, reduce workplace injuries and deaths, contribute to clean air and water, and reduce employment discrimination.
- ✓ Critics of social regulation say uneconomical policy goals, inadequate information, unintended side effects, and overzealous personnel create excessive regulation, for which regulatory costs exceed regulatory benefits.

SUMMARY

L021.1 List and explain the core elements of the major antitrust (antimonopoly) laws in the United States.

The cornerstones of antitrust policy are the Sherman Act of 1890 and the Clayton Act of 1914. The Sherman Act specifies that "every contract, combination . . . or conspiracy in the restraint of interstate trade . . . is . . . illegal" and that any person who monopolizes or attempts to monopolize interstate trade is guilty of a felony.

If a company is found guilty of violating the antimonopoly provisions of the Sherman Act, the government can either break up the monopoly into competing firms (a structural remedy) or prohibit it from engaging in specific anticompetitive business practices (a behavioral remedy).

The Clayton Act was designed to bolster and make more explicit the provisions of the Sherman Act. It declares that price discrimination, tying contracts, intercorporate stock acquisitions, and interlocking directorates are illegal when their effect is to reduce competition.

The Federal Trade Commission Act of 1914 created the Federal Trade Commission to investigate antitrust violations and to prevent the use of "unfair methods of competition." The FTC Act was amended by the Wheeler-Lea Act of 1938 to outlaw false and deceptive representation of products to consumers. Empowered by

cease-and-desist orders, the FTC serves as a watchdog agency over unfair, deceptive, or false claims made by firms about their own products or the products of their competitors.

The Celler-Kefauver Act of 1950 amended the Clayton Act of 1914 to prohibit one firm from acquiring the assets of another firm when doing so would substantially reduce competition.

L021.2 Describe some of the key issues relating to the interpretation and application of antitrust laws.

Some of the key issues in applying antitrust laws include (a) determining whether an industry should be judged by its structure or by its behavior, (b) defining the scope and size of the dominant firm's market, and (c) deciding how strictly to enforce the antitrust laws.

The courts treat price-fixing among competitors as a *per se violation*, meaning that the conduct is illegal independently of whether the conspiracy causes harm. In contrast, a *rule of reason* is used to assess monopoly. Only monopolies that unreasonably (abusively) achieve or maintain their status violate the law. Antitrust officials are more likely to challenge price-fixing, tying contracts, and horizontal mergers than to try to break up existing monopolies. Nevertheless, antitrust suits by the federal government led to the breakup of the AT&T monopoly in the early 1980s.

L021.3 Identify and explain the economic principles and difficulties relating to the setting of prices (rates) charged by so-called natural monopolies.

The objective of industrial regulation is to protect the public from the market power of natural monopolies by regulating prices and quality of service.

Critics of industrial regulation contend that it can lead to inefficiency and rising costs and that in many instances it constitutes a legal cartel for the regulated firms. Legislation passed in the late 1970s and the 1980s has brought about varying degrees of deregulation in the airline, trucking, banking, railroad, and television broadcasting industries.

Studies indicate that deregulation of airlines, railroads, trucking, and telecommunications is producing sizable annual gains to society through lower prices, lower costs, and increased output.

Less certain is the effect of the more recent deregulation of the electricity industry.

L021.4 Discuss the nature of “social regulation,” its benefits and costs, and its optimal level.

Social regulation is concerned with product safety, working conditions, and the effects of production on society. Whereas industrial regulation is on the wane, social regulation continues to expand. The optimal amount of social regulation occurs where $MB = MC$.

People who support social regulation point to its numerous specific successes and assert that it has greatly enhanced society’s well-being. Critics of social regulation contend that businesses are excessively regulated to the point where marginal costs exceed marginal benefits. They also say that social regulation often produces unintended and costly side effects.

DISCUSSION QUESTIONS

- Both antitrust policy and industrial regulation deal with monopoly. What distinguishes the two approaches? How does government decide to use one form of remedy rather than the other? **L021.1, L021.3**
- Describe the major provisions of the Sherman and Clayton acts. What government entities are responsible for enforcing those laws? Are firms permitted to initiate antitrust suits on their own against other firms? **L021.1**
- Contrast the outcomes of the Standard Oil and U.S. Steel cases. What was the main antitrust issue in the DuPont cellophane case? In what major way do the Microsoft and Standard Oil cases differ? **L021.2**
- Why might one administration interpret and enforce the antitrust laws more strictly than another? How might a change of administrations affect a major monopoly case in progress? **L021.2**
- Suppose a proposed merger of firms would simultaneously lessen competition and reduce unit costs through economies of scale. Do you think such a merger should be allowed? **L021.2**
- In the 1980s, PepsiCo Inc., which then had 28 percent of the soft-drink market, proposed to acquire the Seven-Up Company. Shortly thereafter, the Coca-Cola Company, with 39 percent of the market, indicated it wanted to acquire the Dr Pepper Company. Seven-Up and Dr Pepper each controlled about 7 percent of the market. In your judgment, was the government’s decision to block these mergers appropriate? **L021.2**
- Why might a firm charged with violating the Clayton Act, Section 7, try arguing that the products sold by the merged firms are in separate markets? Why might a firm charged with violating Section 2 of the Sherman Act try convincing the court that none of its behavior in achieving and maintaining its monopoly was illegal? **L021.2**
- “The social desirability of any particular firm should be judged not on the basis of its market share but on the basis of its conduct and performance.” Make a counterargument, referring to the monopoly model in your statement. **L021.2**
- What types of industries, if any, should be subjected to industrial regulation? What specific problems does industrial regulation entail? **L021.3**

10. In view of the problems involved in regulating natural monopolies, compare socially optimal (marginal-cost) pricing and fair-return pricing by referring again to Figure 12.9. Assuming that a government subsidy might be used to cover any loss resulting from marginal-cost pricing, which pricing policy would you favor? Why? What problems might such a subsidy entail? **LO21.3**
11. How does social regulation differ from industrial regulation? What types of benefits and costs are associated with social regulation? **LO21.4**
12. Use economic analysis to explain why the optimal amount of product safety may be less than the amount that would totally eliminate the risk of accidents and deaths. Use automobiles as an example. **LO21.4**
13. **LAST WORD** On what basis were the airlines found guilty of violating antitrust laws in the Airline Tariff Publishing case? What was the remedy? By contrast, why might it be hard to prosecute algorithmic collusion, which also uses prices posted electronically?

REVIEW QUESTIONS

1. True or false: Under the “rule of reason” that was established by the Supreme Court in the U.S. Steel case, a monopoly seller should be found guilty of violating antitrust laws even if it is charging low prices to consumers and acting the same way a competitive firm would act. **LO21.2**
2. How would you expect antitrust authorities to react to: **LO21.2**
 - a. A proposed merger of Ford and General Motors.
 - b. Evidence of secret meetings by contractors to rig bids for highway construction projects.
 - c. A proposed merger of a large shoe manufacturer and a chain of retail shoe stores.
 - d. A proposed merger of a small life-insurance company and a regional candy manufacturer.
 - e. An automobile rental firm that charges higher rates for last-minute rentals than for rentals reserved weeks in advance.
3. When confronted with a natural monopoly that restricts output and charges monopoly prices, the two methods that governments have for promoting better outcomes are: **LO21.3**
 - a. Public ownership and public regulation.
 - b. Sole proprietorships and public goods.
 - c. Antitrust law and horizontal mergers.
 - d. Creative destruction and laissez-faire.
4. Which of the following is the correct name for the idea that certain firms prefer government regulation because regulation shields them from the pressures of competition and, in effect, guarantees them a regulated profit. **LO21.3**
 - a. The public interest theory of regulation.
 - b. The structuralists’ theory of monopoly.
 - c. The legal cartel theory of regulation.
 - d. The public regulation theory of natural monopoly.
5. True or false: Economists believe that social regulation is an exception to the $MB = MC$ rule because social regulation should in every case extend as far as possible in order to ensure safe products, less pollution, and improved working conditions. **LO21.4**

PROBLEMS

1. Suppose that there are only three types of fruit sold in the United States. Annual sales are 1 million tons of blueberries, 5 million tons of strawberries, and 10 million tons of bananas. Suppose that of those total amounts, the Sunny Valley Fruit Company sells 900,000 tons of blueberries, 900,000 tons of strawberries, and 7.9 million tons of bananas. **LO21.2**
 - a. What is Sunny Valley’s market share if the relevant market is blueberries? If a court applies the “90-60-30 rule” when considering just the blueberry market, would it rule that Sunny Valley is a monopoly?
 - b. What is Sunny Valley’s market share if the relevant market is all types of berries? Would the court rule Sunny Valley to be a monopolist in that market?
 - c. What if the relevant market is all types of fruit? What is Sunny Valley’s market share, and would the court consider Sunny Valley to be a monopolist?
2. Carrot Computers and its competitors purchase touch screens for their tablet computers from several suppliers. The six makers of touch screens have market shares of, respectively, 19 percent, 18 percent, 14 percent, 16 percent, 20 percent, and 13 percent. **LO21.2**
 - a. What is the Herfindahl index for the touch screen manufacturing industry?
 - b. By how much would a proposed merger between the two smallest touch screen makers increase the Herfindahl index? Would the government be likely to challenge that proposed merger?
 - c. If Carrot Computers horizontally merges with its competitor Blueberry Handhelds, by how much would the Herfindahl index change for the touch screen industry?

Agriculture: Economics and Policy

Learning Objectives

If you eat, you are part of agriculture! In the United States, agriculture is important for a number of reasons. It is one of the nation's largest industries and major segments of it provide real-world examples of the pure-competition model developed in Chapters 10 and 11. Also, agriculture clearly shows the effects of government policies that interfere with supply and demand. Further, the industry provides excellent illustrations of Chapter 5's special-interest effect

and rent-seeking behavior. Finally, it demonstrates the globalization of markets for farm commodities.

This chapter examines the circumstances in agriculture that have resulted in government intervention, the types and outcomes of government intervention, and recent major changes in farm policy.

Economics of Agriculture

LO22.1 Explain why agricultural prices and farm income are unstable.

Although economists refer to *the* agriculture industry, this segment of the economy is extremely diverse. Agriculture encompasses cattle ranches, fruit orchards, dairies, poultry plants, pig farms, grain farms, feed lots, vegetable plots, sugar-cane plantations, and much more. Some farm commodities (for example, soybeans and corn) are produced by thousands of individual farmers. Other farm commodities (such as poultry) are produced by just a handful of large firms. Some farm products (for example, wheat, milk, and sugar) are heavily subsidized through federal government programs; other farm products (such as fruits, nuts, and potatoes) have much less government support.

Moreover, agriculture includes both farm products, or **farm commodities** (for example, wheat, soybeans, cattle, and rice), and also **food products** (items sold through restaurants or grocery stores). Generally, the number of competing firms

in the market diminishes as farm products are refined into commercial food products. Although thousands of ranches and farms raise cattle, only four firms (Tyson, Cargill, JBS, and National) account for about 80 percent of red meat produced at cattle slaughtering/meat packing plants. And thousands of farms grow tomatoes, but only three companies (Heinz, Del-Monte, and Hunt) make the bulk of the ketchup sold in the United States.

Our focus in this chapter will be on farm commodities (or farm products) and the farms and ranches that produce them. Farm commodities usually are sold in highly competitive markets, whereas food products tend to be sold in markets characterized by monopolistic competition or oligopoly.

Partly because of large government subsidies, farming remains a generally profitable industry. U.S. consumers allocate 10 percent of their spending to food, and farmers and ranchers receive about \$380 billion of revenue annually from sales of crops and livestock. Over the years, however, American farmers have experienced severely fluctuating prices and periodically low incomes. Further, they have had to adjust to the reality that agriculture is a declining industry. The farm share of GDP has declined from about 7 percent in 1950 to 1 percent today.

Let's take a close look at both the short-run and long-run economics of U.S. agriculture.

The Short Run: Price and Income Instability

Price and income instability in agriculture results from (1) an inelastic demand for agricultural products, combined with (2) fluctuations in farm output and (3) shifts of the demand curve for farm products.

Inelastic Demand for Agricultural Products In industrially advanced economies, the price elasticity of demand for agricultural products is low. For agricultural products in the aggregate, the elasticity coefficient is between 0.20 and 0.25. These figures suggest that the prices of farm products would have to fall by 40 to 50 percent for consumers to increase their purchases by a mere 10 percent. Consumers apparently put a low value on additional farm output compared with the value they put on additional units of alternative goods.

Why is this so? Recall that the basic determinant of elasticity of demand is substitutability. When the price of one product falls, the consumer tends to substitute that product for other products whose prices have not fallen. But in relatively wealthy societies this “substitution effect” is very modest for food. Although people may eat more, they do not switch from three meals a day to, say, five or six meals a day in response to a decline in the relative prices of farm products. Real biological factors constrain an individual's capacity to substitute food for other products.

The inelasticity of agricultural demand is also related to diminishing marginal utility. In a high-income economy, the population is generally well fed and well clothed; it is relatively saturated with the food and fiber of agriculture. Additional farm products therefore are subject to rapidly diminishing marginal utility. So very large price cuts are needed to induce small increases in food and fiber consumption.

Fluctuations in Output Farm output tends to fluctuate from year to year, mainly because farmers have limited control over their output. Floods, droughts, unexpected frost, insect damage, and similar disasters can mean poor crops, while an excellent growing season means bumper crops (unusually large outputs). Such natural occurrences are beyond the control of farmers, yet they exert an important influence on output.

In addition to natural phenomena, the highly competitive nature of many parts of farming and ranching makes it difficult for those producers to form huge combinations to control production. If the thousands of widely scattered and independent producers happened to plant an unusually large or abnormally small portion of their land one year, an extra-large or a very small farm output would result even if the growing season were normal.

Curve D in Figure 22.1 illustrates the inelastic demand for agricultural products. Combining that inelastic demand with the instability of farm production, we can see why agricultural prices and incomes are unstable. Even if the market demand for farm products remains fixed at D , its price inelasticity will magnify small changes in output into relatively large changes in agricultural prices and income. For example, suppose that a “normal” crop of Q_n results in a “normal” price of P_n and a “normal” farm income represented by the yellow rectangle. A bumper crop or a poor crop will cause large deviations from these normal prices and incomes because of the inelasticity of demand.

If a good growing season occurs, the resulting large crop of Q_b will reduce farm income to that of area $0P_b bQ_b$. When demand is inelastic, an increase in the quantity sold will be accompanied by a more-than-proportionate decline in price. The net result is that total revenue, that is, total farm income, will decline disproportionately.

Similarly, a small crop caused by, say, drought will boost total farm income to that represented by area $0P_p pQ_p$. A decline in output will cause more-than-proportionate increases in price and income when demand is inelastic. Ironically, for farmers as a group, a poor crop may be a blessing and a bumper crop a hardship.

Conclusion: With a stable market demand for farm products, the inelasticity of that demand will turn relatively small changes in output into relatively larger changes in agricultural prices and income.

FIGURE 22.1 The effects of changes in farm output on agricultural prices and income. Because of the inelasticity of demand for farm products, a relatively small change in farm output (from Q_n to Q_p or Q_b) will cause a relatively large change in agricultural prices (from P_n to P_p or P_b). Farm income will change from the yellow area to the larger OP_pPQ_p area or to the smaller OP_bPQ_b area.

FIGURE 22.2 The effect of a demand shift on agricultural prices and income. Because of the highly inelastic demand for farm products, a small shift in demand (from D_1 to D_2) for farm products can drastically alter agricultural prices (P_1 to P_2) and farm income (area OP_1aQ_n to area OP_2bQ_n), given a fixed level of production Q_n .

Fluctuations in Demand The third factor in the short-run instability of farm income results from shifts in the demand curve for agricultural products. Suppose that somehow farm output is stabilized at the “normal” level of Q_n in Figure 22.2. Now, because of the inelasticity of the demand for farm products, short-run changes in the demand for those products will

cause markedly different prices and incomes to be associated with this fixed level of output.

A slight decline in demand from D_1 to D_2 will reduce farm income from area OP_1aQ_n to OP_2bQ_n . So a relatively small decline in demand gives farmers significantly less income for the same amount of farm output. Conversely, a slight increase in

FIGURE 22.3 U.S. farm exports as a percentage of farm output, 1950–2014. Exports of farm output have increased as a percentage of total farm output (the value of agricultural-sector production) in the United States. But this percentage has been quite variable, contributing to the instability of the demand for U.S. farm output.

demand—as from D_2 to D_1 —provides a sizable increase in farm income for the same volume of output. Again, large price and income changes occur because demand is inelastic.

It is tempting to argue that the sharp declines in agricultural prices that accompany a decrease in demand will cause many farmers to close down in the short run, reducing total output and alleviating the price and income declines. But farm production is relatively insensitive to price changes in the short run because farmers' fixed costs are high compared with their variable costs.

Interest, rent, tax, and mortgage payments on land, buildings, and equipment are the major costs faced by the farmer. These are all fixed charges. Furthermore, the labor supply of farmers and their families can also be regarded as a fixed cost. As long as they stay on their farms, farmers cannot reduce their costs by firing themselves. Their variable costs are the costs of the small amounts of extra help they may employ, as well as expenditures for seed, fertilizer, and fuel. As a result of their high proportion of fixed costs, farmers are usually better off working their land even when they are losing money since they would lose much more by shutting down their operations for the year. Only in the long run will exiting the industry make sense for them.

But why is agricultural demand unstable? The major source of demand volatility in U.S. agriculture springs from

its dependence on world markets. As we show in Figure 22.3, that dependency has increased since 1950. The yearly ups and downs of the line in the figure also reveal that, as a percentage of total U.S. farm output, farm exports are highly unstable.

The incomes of U.S. farmers are sensitive to changes in weather and crop production in other countries: Better crops abroad mean less foreign demand for U.S. farm products. Similarly, cyclical fluctuations in incomes in Europe or Southeast Asia, for example, may shift the demand for U.S. farm products. Changes in foreign economic policies may also change demand. For instance, if the nations of western Europe decide to provide their farmers with greater protection from foreign competition, U.S. farmers will have less access to those markets and demand for U.S. farm exports will fall.

International politics also add to demand instability. Changing political relations between the United States and China and the United States and Russia have boosted exports to those countries in some periods and reduced them in others. Changes in the international value of the dollar may also be critical. Depreciation of the dollar increases the demand for U.S. farm products (which become cheaper to foreigners), whereas appreciation of the dollar diminishes foreign demand for U.S. farm products.

Figure 22.4 shows inflation-adjusted U.S. prices for cattle, hogs, corn, and wheat from 1950 through 2012. The

short-run economics of price volatility is evident. So, too, is the general decline of real (inflation-adjusted) agricultural prices from 1950 through the late 1990s.

Since the late 1990s, however, the prices of these four commodities have not continued the overall downward trend that they had previously followed. Prices continued to be volatile but remained in 2009 about where they had been in the late 1990s. Then, major price spikes took place between 2009 and 2012. For example, the inflation-adjusted price of wheat more than doubled, increasing from \$3.75 per bushel in 2009 to \$8.31 per bushel in 2012.

The lack of a downward trend in commodity prices starting in the late 1990s coupled with the major price spikes that occurred between 2009 and 2012 led some economists to wonder whether the era of inflation-adjusted price decreases in agriculture had come to an end. They speculated that the rising demand for food in emerging economies such as China together with the growing demand for farm products to produce ethanol might reverse the long-run downward trend. But, as Figure 22.4 reveals, several previous price spikes as well as flat periods in agricultural prices have occurred. Each of these events eventually yielded to the general historical downward trend in agricultural prices. That patterned reoccurred between 2012 and 2015 as the prices of hogs, corn, and wheat fell back down toward their all-time lows.

The Long Run: A Declining Industry

LO22.2 Discuss why there has been a huge employment exodus from agriculture to other U.S. industries over the past several decades.

Two dynamic characteristics of agricultural markets explain why agriculture has been a declining industry:

- Over time, the supply of farm products has increased rapidly because of technological progress.
- The demand for farm products has increased slowly because it is inelastic with respect to income and because it is largely limited by population growth, which has not been rapid in the United States.

Let's examine each of these supply and demand forces.

Technology and Supply Increases

A rapid rate of technological advance has significantly increased the supply of agricultural products. This technological progress has many roots: the mechanization of farms, improved techniques of land management, soil conservation, irrigation, development of hybrid crops, availability of improved fertilizers and insecticides, polymer-coated seeds, and improvements in the breeding and care of livestock. The amount of capital used per farmworker increased 15 times between 1930 and 1980,

permitting a fivefold increase in the amount of land cultivated per farmer. The simplest measure of these advances is the U.S. Agriculture Department's index of farm output per unit of farm labor. In 1950 a single unit of farm labor could produce 10 units of farm output. This amount increased to 30 in 1970, 42 in 1980, 64 in 1990, 90 in 2000, and 119 in 2009. Over the last half-century, productivity in agriculture has advanced twice as fast as productivity in the nonfarm economy.

Most of the technological advances in agriculture were not initiated by farmers. Rather, they are the result of government-sponsored programs of research and education and the initiative of the suppliers of farm inputs. Land-grant colleges, experiment stations, county agents of the Agricultural Extension Service, educational pamphlets issued by the U.S. Department of Agriculture (USDA), and the research departments of farm machinery, pesticide, and fertilizer producers have been the primary sources of technological advance in U.S. agriculture.

More recently, technological advance has been fueled by the incorporation of advanced information technologies into farming. Computers and the Internet give farmers instant access to information about soil conditions, estimated crop yields, farm-product prices, available land for purchase or lease, and much more. They also provide farmers with sophisticated business software to help track and manage their operations.

Lagging Demand

Increases in the demand for agricultural products have failed to keep pace with these technologically created increases in the supply of the products. The reason lies in the two major determinants of agricultural demand: income and population.

In developing countries, consumers must devote most of their meager incomes to agricultural products—food and clothing—to sustain themselves. But as income expands beyond subsistence and the problem of hunger diminishes, consumers increase their outlays on food at ever-declining rates. Once consumers' stomachs are filled, they turn to the amenities of life that manufacturing and services, not agriculture, provide. Economic growth in the United States has boosted average per capita income far beyond the level of subsistence. As a result, increases in the incomes of U.S. consumers now produce less-than-proportionate increases in spending on farm products.

The demand for farm products in the United States is income-inelastic; it is quite insensitive to increases in income. Estimates indicate that a 10 percent increase in real per capita after-tax income produces about a 1 percent increase in consumption of farm products. That means a coefficient of income elasticity of 0.1 ($= 0.01/0.10$). So as the incomes of Americans rise, the demand for farm products increases far less rapidly than the demand for goods and services in general.

The second reason for lagging demand relates to population growth. Once a certain income level has been reached, each consumer's intake of food and fiber becomes relatively

Later in this chapter we will find that farm programs (direct payments, countercyclical payments, and “repay-or-default” loans) reduce the risk of farming for many farmers. But these programs are limited to certain crops, such as grains and oilseeds.

Fortunately, several private techniques for managing risk have become commonplace in agriculture. The purpose of these measures is to “smooth” income over time, “hedging” against short-run output and price fluctuations. Hedging is an action by a buyer or seller to protect against a change in future prices prior to an anticipated purchase or sale.

Farm risk-management techniques include:

- **Futures markets.** In the futures market, farmers can buy or sell farm products at prices fixed now, for delivery at a specified date in the future. If the price falls, farmers will still obtain revenue based on the higher price fixed in the futures market. If the price rises, the buyer will benefit by getting the farm commodity at the lower price fixed in the futures market.
- **Contracting with processors.** In advance of planting, farmers can directly contract with food processors (firms such as sugar beet refiners, ethanol plants, and feed lots) to assure themselves of a fixed price per unit of their farm or ranch output.
- **Crop revenue insurance.** Farmers can buy crop revenue insurance, which insures them against gross revenue losses resulting from storm damage and other natural occurrences.
- **Leasing land.** Farm operators can reduce their risk by leasing some of their land to other operators who pay them cash rent. The rent payment is stable, regardless of the quality of the crop and crop prices.
- **Nonfarm income.** Many farm households derive substantial parts of their total income from off-farm income, such as spousal work and agricultural investments. These more-stable elements of income cushion the instability of farm income.

Although farming remains a risky business, farm operators have found creative ways to manage the inherent risks of price and income instability.

Risky Business

The short-run instability of agricultural prices and farm income creates considerable risk in agriculture.

FIGURE 22.5 The long-run decline of agricultural prices and farm income. In the long run, increases in the demand for U.S. farm products (from D_1 to D_2) have not kept pace with the increases in supply (from S_1 to S_2) resulting from technological advances. Because agricultural demand is inelastic, these shifts have tended to depress agricultural prices (from P_1 to P_2) and reduce farm income (from OP_1aQ_1 to OP_2bQ_2) while increasing output only modestly (from Q_1 to Q_2).

products increases at a rate roughly equal to the rate of population growth. Because U.S. population growth has not been rapid, the increase in U.S. demand for farm products has not kept pace with the rapid growth of farm output.

Graphical Portrayal

The combination of an inelastic and slowly increasing demand for agricultural products with a rapidly increasing supply puts strong downward pressure on agricultural prices and income. Figure 22.5 shows a large increase in agricultural supply accompanied by a very modest increase in demand. Because of the inelasticity of demand, those shifts result in a sharp decline in agricultural prices, accompanied by a relatively small increase in output. So farm income declines. On the graph, we see that farm income before the increases in demand and supply (measured by rectangle OP_1aQ_1) exceeds farm income after those increases (OP_2bQ_2). Because farm products have inelastic demand, an increase in supply relative to demand creates persistent downward pressure on farm income.

Consequences

The actual consequences of the demand and supply changes over time have been those predicted by the pure-competition model. The supply and demand conditions just outlined have increased the minimum efficient scale (MES) in agriculture and reduced crop prices. Farms that are too small to realize productivity gains and take advantage of economies of scale have discovered that their average total costs exceed the (declining) prices for their crops. So they can no longer operate

fixed. Thus subsequent increases in demand depend directly on growth in the number of consumers. In most advanced nations, including the United States, the demand for farm

profitably. In the long run, financial losses in agriculture have triggered a massive exit of workers to other sectors of the economy, as shown by Table 22.1. They have also caused a major consolidation of smaller farms into larger ones. A person farming, say, 240 acres of corn three decades ago is today likely to be farming two or three times that number of acres. Large corporate firms, collectively called **agribusiness**, have emerged in some areas of farming such as potatoes, beef, fruits, vegetables, and poultry. Today, there are 2.1 million farms compared to about 4 million in 1960, and farm labor constitutes about 1.5 percent of the U.S. labor force compared to 9.4 percent in 1960. (Global Perspective 22.1 compares the most recent labor-force percentages for several nations.)

Farm-Household Income

Traditionally, the income of farm households was well below that of nonfarm households. But even with the lower real crop prices, that imbalance has reversed. In 2014—a particularly good year for agriculture—the average income of farm households was about \$134,000, compared to \$75,738 for all U.S. households. Outmigration, consolidation, rising farm productivity, and significant government subsidies have boosted farm income *per farm household* (of which there are fewer than before).

Also, members of farm households operating smaller farms have increasingly taken jobs in nearby towns and cities. On average, only about 16 percent of the income of farm households derives from farming activities. This average, however, is pulled downward by the many households living in rural areas and operating small “residential farms.” For households operating “commercial farms”—farms with

High-income nations devote a much smaller percentage of their labor forces to agriculture than do low-income nations. Because their workforces are so heavily committed to producing the food and fiber needed for their populations, low-income nations have relatively less labor available to produce housing, schools, autos, and the other goods and services that contribute to a high standard of living.

annual sales of \$350,000 or more—about 73 percent of the average income of \$225,463 in 2014 derived from farming. Although agriculture is a declining industry, the 10 percent of farm households operating commercial farms in the United States are doing remarkably well, at least as a group.

QUICK REVIEW 22.1

- ✓ Agricultural prices and incomes are volatile in the short run because an inelastic demand converts small changes in farm output and demand into relatively larger changes in prices and income.
- ✓ Technological progress has generated large increases in the supply of farm products over time.
- ✓ Increases in demand for farm products have been modest in the United States because demand is inelastic with respect to income and because population growth has been modest.
- ✓ The combination of large increases in supply and small increases in demand has made U.S. agriculture a declining industry (as measured by the value of agricultural output as a percentage of GDP).

Economics of Farm Policy

L022.3 Relate the rationale for farm subsidies and the economics and politics of price supports (price floors).

The U.S. government has subsidized agriculture since the 1930s with a “farm program” that includes (1) support for agricultural prices, income, and output; (2) soil and water conservation; (3) agricultural research; (4) farm credit; (5) crop insurance; and (6) subsidized sale of farm products in world markets.

We will focus on the main element of farm policy: the programs designed to prop up prices and income. This topic is particularly timely because in recent years (specifically, 1996, 2002, 2008, and 2014), Congress passed new farm laws replacing traditional forms of farm subsidies with new forms. To understand these new policies, we need to understand the policies they replaced and the purposes and outcomes of farm subsidies. Between 2002 and 2011, American farmers received an average of about \$20.0 billion of direct government subsidies each year. (As indicated in Global Perspective 22.2, farm subsidies are common in many nations.)

Rationale for Farm Subsidies

A variety of arguments have been made to justify farm subsidies over the decades:

- Although farm products are necessities of life, many farmers have relatively low incomes, so they should receive higher prices and incomes through public help.
- The “family farm” is a fundamental U.S. institution and should be nurtured as a way of life.
- Farmers are subject to extraordinary hazards—floods, droughts, and insects—that most other industries do not face. Without government help, farmers cannot fully insure themselves against these disasters.
- While many farmers face purely competitive markets for their outputs, they buy inputs of fertilizer, farm machinery, and gasoline from industries that have considerable market power. Whereas those resource-supplying industries are able to control their prices, farmers are at the “mercy of the market” in selling their output. The supporters of subsidies argue that agriculture warrants public aid to offset the disadvantageous market-power imbalances faced by farmers.

Background: The Parity Concept

The Agricultural Adjustment Act of 1933 established the **parity concept** as a cornerstone of agricultural policy. The rationale of the parity concept can be stated in both real and nominal terms. In real terms, parity says that year after year for a fixed output of farm products, a farmer should be able to

GLOBAL PERSPECTIVE 22.2

acquire a specific total amount of other goods and services. A particular real output should always result in the same real income: “If a farmer could take a bushel of corn to town in 1912 and sell it for enough money to buy a shirt, he should be able to sell a bushel of corn today and buy a shirt.” In nominal terms, the parity concept suggests that the relationship between the prices received by farmers for their output and the prices they must pay for goods and services should remain constant. The parity concept implies that if the price of shirts tripled over some time period, then the price of corn should have tripled too. Such a situation is said to represent 100 percent of parity.

The **parity ratio** is the ratio of prices received to prices paid, expressed as a percentage. That is:

$$\text{Parity ratio} = \frac{\text{Prices received by farmers}}{\text{Prices paid by farmers}}$$

Why farmers would benefit from having the prices of their products based on 100 percent of parity is obvious. By 2015 nominal prices paid by farmers had increased 29-fold since 1900–1914, whereas nominal prices received by farmers had increased only about 9-fold. In 2015 the parity ratio stood at 0.36 (or 36 percent), indicating that prices received in 2015 could buy 36 percent as much as prices received in the 1910–1914 period. So a farm policy that enforced 100 percent of parity would generate substantially higher prices for farmers.

FIGURE 22.6 Price supports, agricultural surpluses, and transfers to farmers. The market demand D and supply S of a farm product yield equilibrium price P_e and quantity Q_e . An above-equilibrium price support P_s results in consumption of quantity Q_c , production of quantity Q_s , and a surplus of quantity $Q_s - Q_c$. The yellow rectangle represents a transfer of money from taxpayers to farmers. Triangle bac within the yellow rectangle shows the efficiency loss (or a deadweight loss) to society.

Economics of Price Supports

The concept of parity provides the rationale for government price floors on farm products. In agriculture those minimum prices are called **price supports**. We have shown that, in the long run, the market prices received by farmers have not kept up with the prices paid by them. One way to achieve parity, or some percentage thereof, is to have the government establish above-equilibrium price supports for farm products.

Many different price-support programs have been tried, but they all tend to have similar effects, some of which are subtle and negative. Suppose in Figure 22.6 that the equilibrium price is P_e and the price support is P_s . Then the major effects would be as follows.

Surplus Output The most obvious result is a product surplus. Consumers are willing to purchase only Q_c units at the supported price, while farmers supply Q_s units. What about the $Q_s - Q_c$ surplus that results? The government must buy it to make the above-equilibrium price support effective. As you will see, this surplus farm output means that agriculture receives an overallocation of resources.

Gain to Farmers Farmers benefit from price supports. In Figure 22.6, gross farm revenue rises from the free-market level represented by area $OP_e b Q_e$ to the larger, supported level shown by area $OP_s a Q_s$.

Loss to Consumers Consumers lose; they pay a higher price (P_s rather than P_e) and consume less (Q_c rather than Q_e) of the product. In some instances differences between the market price and the supported price are substantial. For example, the U.S.-supported price of a pound of sugar is about 32 percent higher than the world market price, and a quart of fluid milk is estimated to cost consumers twice as much as it would without government programs. Moreover, the burden of higher food prices falls disproportionately on the poor because they spend a larger part of their incomes on food.

Efficiency Losses Society loses because price supports create allocative inefficiency by encouraging an overallocation of resources to agriculture. A price floor (P_s) attracts more resources to the agricultural sector than would the free-market price (P_e). Viewed through the pure-competition model, the market supply curve in Figure 22.6 represents the marginal costs of all farmers producing this product at the various output levels. An efficient allocation of resources occurs at point b , where the market price P_e is equal to marginal cost. So the output Q_e reflects that efficient allocation of resources.

In contrast, the output Q_s associated with the price support P_s represents an overallocation of resources; for all units of output between Q_e and Q_s , marginal costs (measured on curve S) exceed the prices people are willing to pay for those units (measured on curve D). Simply stated, the marginal cost of the extra production exceeds its marginal benefit to society. Society incurs an efficiency loss (or a deadweight loss) of area bac because of the price-support system.

Other Social Losses Society at large loses in other ways. Taxpayers pay higher taxes to finance the government's purchase of the surplus. This added tax burden is equal to the surplus output $Q_s - Q_c$ multiplied by its price P_s , as shown by the yellow area in Figure 22.6. Recall, too, that the mere collection of taxes imposes an efficiency loss (as was demonstrated in Chapter 20 in Figure 20.10). Also, the cost of storing surplus farm output adds to this tax burden.

Government's intervention in agriculture also entails administrative costs. Thousands of government workers are needed to administer U.S. price supports and other farm programs.

Finally, the rent-seeking activity involved—the pursuit of political support to maintain price supports—is costly and socially wasteful. Farm groups spend considerable sums to sustain political support for price floors and other programs that enhance farm incomes.

Environmental Costs We know from Figure 22.6 that price supports encourage additional production. Although some of that extra output may come from the use of additional land, much of it comes from heavier use of fertilizer and pesticides. Those pesticides and fertilizers may pollute

the environment (for example, groundwater) and create residues in food that pose health risks to farmworkers and consumers. Research shows a positive relationship between the level of price-support subsidies and the use of agrochemicals.

Farm policy also may cause environmental problems in less obvious ways. Farmers benefit from price supports only when they use their land consistently for a specific crop such as corn or wheat. That creates a disincentive to practice crop rotation, which is a nonchemical technique for controlling pests. Farm policy thus encourages the substitution of chemicals for other forms of pest control.

Also, we know from the concept of derived demand that an increase in the price of a product will increase the demand for relevant inputs. In particular, price supports for farm products increase the demand for land. And the land that farmers bring into farm production is often environmentally sensitive “marginal” land, such as steeply sloped, erosion-prone land, or wetlands that provide wildlife habitat. Similarly, price supports result in the use of more water for irrigation, and the resulting runoff may contribute to soil erosion.

International Costs Actually, the costs of farm price supports go beyond those indicated by Figure 22.6. Price supports generate economic distortions that cross national boundaries. For example, the high prices caused by price supports make the U.S. agricultural market attractive to foreign producers. But inflows of foreign agricultural products would serve to increase supplies in the United States, aggravating the problem of U.S. surpluses. To prevent that from happening, the United States is likely to impose import barriers in the form of tariffs or quotas. Those barriers tend to restrict the output of more-efficient foreign producers while encouraging more output from less-efficient U.S. producers. The result is a less-efficient use of world agricultural resources. This chapter’s Last Word suggests that this is indeed the case for sugar.

Similarly, as the United States and other industrially advanced countries with similar agricultural programs dump surplus farm products on world markets, the prices of such products are depressed. Developing countries are often heavily dependent on world commodity markets for their incomes. So they are particularly hurt because their export earnings are reduced. Thus, U.S. subsidies for rice production have imposed significant costs on Thailand, a major rice exporter. Similarly, U.S. cotton programs have adversely affected Egypt, Mexico, and other cotton-exporting nations.

Reduction of Surpluses

Figure 22.6 suggests that programs designed to reduce market supply (shift S leftward) or increase market demand (shift D rightward) would help boost the market price toward

the supported price P_s . Further, such programs would reduce or eliminate farm surpluses. The U.S. government has tried both supply and demand approaches to reduce or eliminate surpluses.

Restricting Supply Until recently, public policy focused mainly on restricting farm output. In particular, **acreage allotments** accompanied price supports. In return for guaranteed prices for their crops, farmers had to agree to limit the number of acres they planted in that crop. The U.S. Department of Agriculture first set the price support and then estimated the amount of the product consumers would buy at the supported price. It then translated that amount into the total number of planted acres necessary to provide it. The total acreage was apportioned among states, counties, and ultimately individual farmers.

These supply-restricting programs were only partially successful. They did not eliminate surpluses, mainly because acreage reduction did not result in a proportionate decline in production. Some farmers retired their worst land and kept their best land in production. They also cultivated their tilled acres more intensively. Superior seed, more and better fertilizer and insecticides, and improved farm equipment were used to enhance output per acre. And nonparticipating farmers expanded their planted acreage in anticipation of overall higher prices. Nevertheless, the net effect of acreage allotment undoubtedly was a reduction of farm surpluses and their associated costs to taxpayers.

Bolstering Demand Government has tried several ways to increase demand for U.S. agricultural products. For example, both government and private industry have spent large sums on research to create new uses for agricultural goods. The production of “gasohol,” which is a blend of gasoline and alcohol (ethanol) made mainly from corn, is one such successful attempt to increase the demand for farm output. (See the nearby Consider This box for a fuller discussion of ethanol.) Recent attempts to promote “biodiesel,” a fuel made from soybean oil and other natural vegetable oils, also fit the demand-enhancement approach.

The government has also created a variety of programs to stimulate consumption of farm products. For example, the objective of the food-stamp program is not only to reduce hunger but also to bolster the demand for food. Similarly, the Food for Peace program has enabled developing countries to buy U.S. surplus farm products with their own currencies, rather than having to use dollars. The federal government spends millions of dollars each year to advertise and promote global sales of U.S. farm products. Furthermore, U.S. negotiators have pressed hard in international trade negotiations to persuade foreign nations to reduce trade barriers to the importing of farm products.

Putting Corn in Your Gas Tank

Government's promotion of greater production and use of corn-based ethanol serves both as a good example of an attempt by government to bolster the demand for U.S. farm products and as an example of how price changes can ripple through markets and produce myriad secondary effects. Gasoline producers blend ethanol (an alcohol-like substance) with conventional gasoline refined from oil. The government's rationale for promoting ethanol is to reduce U.S. dependency on foreign oil, but the strongest proponents are from states in the Corn Belt.

The ethanol program has several facets, including tariffs on imported ethanol, subsidies to oil refineries that buy ethanol, and mandates to industry to increase their use of alternative fuels. The rising demand for ethanol that resulted contributed to tripling of the inflation-adjusted price of a bushel of corn between 2005 and 2012.

But numerous secondary effects from the increased price of corn also occurred. Farmers shifted production toward corn and away from soybeans, sorghum, and other crops. The decreases in the supply of these other crops raised their prices, too. Also, because corn is used as a major feedstock, the price of beef, pork, and chicken rose.

The ethanol subsidies had other secondary effects. The prices of seed, fertilizer, and farmland all increased. Because corn is a water-intensive crop, its expanded production resulted in faster withdrawals of irrigation water from underground aquifers. The refining of ethanol also depleted ground water or removed it from rivers. Moreover, the increased use of fertilizer in corn production increased the runoff of nitrogen from fertilizer into streams and rivers, causing environmental damage.

The price effects of ethanol subsidies, however, may moderate as farmers shift additional land to corn, increasing its supply and reducing its price. Nevertheless, the multiple impacts of public policy illustrate an important economic maxim: In the economy, it is difficult to do just *one* thing.

During the era of price supports, the government's supply-restricting and demand-increasing efforts boosted agricultural prices and reduced surplus production, but they did not succeed in eliminating the sizable surpluses.

QUICK REVIEW 22.2

- ✓ The parity concept suggests that farmers should obtain a constant ratio of the prices they receive for their farm products and the prices they pay for goods and services in general.
- ✓ Price supports are government-imposed price floors (minimum prices) on selected farm products.
- ✓ Price supports cause surplus production (which the government must buy and store), raise farm income, increase food prices to consumers, and overallocate resources to agriculture.
- ✓ Domestic price supports encourage nations to erect trade barriers against imported farm products and to dump surplus farm products on world markets.

Criticisms and Politics

L022.4 Describe major criticisms of the price-support system in agriculture.

After decades of experience with government price-support programs, it became apparent in the 1990s that farm policy was not working well. Major criticisms of farm subsidies emerged, as did a more skeptical analysis of the politics of those subsidies.

Criticisms of the Parity Concept

Economists uniformly rejected the rationale of the parity concept. They found no economic logic in the proposition that if a bushel of wheat could buy a shirt in 1900, it should still be able to buy a shirt several decades later. The relative values of goods and services are established by supply and demand, and those relative values change over time as technology changes, resource prices change, tastes change, and substitute resources and new products emerge. A fully equipped personal computer, monitor, and printer cost as much as a cheap new automobile in 1985. That was not true just a decade later because the price of computer equipment had dropped so dramatically. Based on the parity concept, one could argue that price supports and subsidies were justified for computer manufacturers!

Criticisms of the Price-Support System

Criticisms of the price-support system were equally severe.

Symptoms, Not Causes The price-support strategy in agriculture was designed to treat the symptoms, not the causes of the farm problem. The root cause of the long-run farm problem was misallocation of resources between agriculture and the rest of the economy. Historically, the problem had

been one of too many farmers. The effect of that misallocation was relatively low agricultural prices and low farm income. But the price and income supports encouraged people to stay in farming rather than move to nonfarm occupations. That is, the price and income orientation of the farm program slowed the reallocation of resources necessary to resolve the long-run farm problem.

Misguided Subsidies Because price supports were on a per-bushel basis, the subsidy system benefited those farmers who needed subsidies the least. If the goal of farm policy was to raise low farm incomes, it followed that any program of federal aid should have been aimed at farmers with the lowest incomes. But the poor, low-output farmer did not produce and sell enough in the market to get much aid from price supports. Instead, the large, prosperous farmer reaped the benefits because of sizable output. On equity grounds, direct income payments to struggling farmers are highly preferable to indirect price-support subsidies that go primarily to large-scale, prosperous farmers. Better yet, say many economists, would be transition and retraining support for farmers willing to move out of farming and into other occupations and businesses in greater demand.

A related point concerns land values. The price and income benefits that the price-support system provided increased the value of farmland. By making crops more valuable, price supports made the land itself more valuable. That was helpful to farmers who owned the land they farmed but not to farmers who rented land. Farmers rented about 40 percent of their farmland, mostly from well-to-do nonfarm landlords. So, price supports became a subsidy to people who were not actively engaged in farming.

Policy Contradictions Because farm policy had many objectives, it often led to contradictions. Whereas most subsidized research was aimed at increasing farm productivity and the supply of farm products, acreage-allotment programs required that farmers take land out of production in order to reduce supply. Price supports for crops meant increased feed costs for ranchers and farmers and high consumer prices for animal products. Tobacco farmers were subsidized even though tobacco consumption was causing serious health problems. The U.S. sugar program raised prices for domestic producers by imposing import quotas that conflicted with free-trade policies. Conservation programs called for setting aside land for wildlife habitat, while price supports provided incentives to bring such acreage into production.

All these criticisms helped spawn policy reform. Nevertheless, as we will see, those reforms turned out to be less substantive than originally conceived. Nearly all these criticisms are as valid for current farm policy as they were for the price-support program.

The Politics of Farm Policy

In view of these criticisms, why did the United States continue its price-support program for 60 years and why does it still continue that program for sugar, milk, and tobacco? Why do farm subsidies in the billions of dollars still occur?

Public Choice Theory Revisited Public choice theory (Chapter 5) helps answer these questions. Recall that rent-seeking behavior occurs when a group (a labor union, firms in a specific industry, or farmers producing a particular crop) uses political means to transfer income or wealth to itself at the expense of another group or of society as a whole. And recall that the special-interest effect involves a program or policy from which a small group receives large benefits at the expense of a much larger group whose members individually suffer small losses. Both rent-seeking behavior and the special-interest effect help explain the politics of farm subsidies.

Suppose a certain group of farmers, say, peanut or sugar producers, organize and establish a well-financed political action committee (PAC). The PAC's job is to promote government programs that will transfer income to the group (this is rent-seeking behavior). The PAC vigorously lobbies U.S. senators and representatives to enact or to continue price supports, production quotas, or import quotas for peanuts or sugar. The PAC does this in part by making political contributions to sympathetic legislators. Although peanut production is heavily concentrated in a few states such as Georgia, Alabama, and Texas, the peanut PAC will also make contributions to legislators from other states in order to gain support.

But how can a small interest group like peanut or sugar growers successfully lobby to increase its own income at the expense of society as a whole? Because even though the total cost of the group's programs might be considerable, the cost imposed on each individual taxpayer is small (this is the special-interest effect). Taxpayers are likely to be uninformed about and indifferent to such programs since they have little at stake. Unless you grow sugar beets or peanuts, you probably have no idea how much these programs cost you as an individual taxpayer and consumer and therefore do not object when your legislator votes for, say, a sugar-support program. Thus, the PAC encounters little or no lobbying against its efforts.

Political logrolling—the trading of votes on policies and programs—also works to perpetuate certain programs: Senator Foghorn agrees to vote for a program that benefits Senator Moribund's constituents, and Moribund returns the favor. Example: Many members of Congress who represent low-income urban areas vote in favor of farm subsidies. In return, representatives of agricultural areas support such programs as food stamps, which subsidize food for the poor. The result is a rural-urban coalition through which representatives from both areas provide benefits for their constituents and

enhance their reelection chances. Such coalitions help explain why farm subsidies persist and why the food-stamp program has been expanded over the years.

Large agribusinesses that supply inputs to agriculture also lend political support to farm subsidies because subsidies increase the amounts of agrochemicals and farm machinery that farmers are able to buy. And most of the thousands of government employees whose jobs depend on farm programs are highly supportive. So, too, are owners of farmland.

Public choice theory also tells us that politicians are likely to favor programs that have hidden costs. As we have seen, that is often true of farm programs. Our discussion of Figure 22.6 indicated that price supports involve not simply a transfer of money from taxpayer to farmer but costs that are hidden as higher food prices, storage costs for surplus output, costs of administering farm programs, and costs associated with both domestic and international misallocations of resources. Because those costs are largely indirect and hidden, farm programs are much more acceptable to politicians and the public than they would be if all costs were explicit.

Changing Politics In spite of rent seeking, special interests, and logrolling, a combination of factors has somewhat altered the politics of farm subsidies in recent decades.

Declining Political Support As the farm population declines, agriculture's political power weakens. The farm population was about 25 percent of the general population in the 1930s, when many U.S. farm programs were established; now it is less than 2 percent. Urban congressional representatives now constitute a 10-to-1 majority over their rural colleagues. An increasing number of legislators are critically examining farm programs for their effects on consumers' grocery bills as well as on farm incomes. Also, more farmers themselves are coming to resent the intrusion of the federal government into their farming decisions. A few rural-state congressional members now support free-market agriculture.

World Trade Considerations The United States has taken the lead to reduce barriers to world trade in agricultural products. This has also contributed to the more critical attitude toward farm subsidies, particularly price supports. The nations of the European Union (EU) and many other nations support agricultural prices. And, to maintain their high domestic prices, they restrict imports of foreign farm products by imposing tariffs and quotas. They then try to rid themselves of their domestic surpluses by subsidizing exports into world markets. The effects on the United States are that (1) trade barriers hinder U.S. farmers from selling to EU nations and (2) subsidized exports from those nations depress world prices for agricultural products, making world markets less attractive to U.S. farmers.

Perhaps most important, farm programs such as those maintained by the EU and the United States distort both world agricultural trade and the international allocation of agricultural resources. Encouraged by artificially high prices, farmers in industrially advanced nations produce more food and fiber than they would otherwise. The resulting surpluses flow into world markets, where they depress prices. This means that farmers in countries with no farm programs—many of them developing countries—face artificially low prices for their exports, which signals them to produce less. Overall, the result is a shift in production away from what would occur on the basis of comparative advantage. As an example, price supports cause U.S. agricultural resources to be used for sugar production, even though sugar can be produced at perhaps half the cost in the Caribbean countries and Australia.

Recognizing these distortions, in 1994 the 128 nations then belonging to the World Trade Organization (WTO) agreed to reduce farm price-support programs by 20 percent by the year 2000 and to reduce tariffs and quotas on imported farm products by 15 percent. Larger, more significant, reductions of farm subsidies and agricultural tariffs are part of the agenda of the most recent round of trade negotiations (the Doha Development Agenda). But reaching agreement on those reductions has proved difficult. As of late 2016, negotiations over these issues were completely stalled.

Recent Farm Policies

L022.5 List the main elements of existing federal farm policy. In the mid-1990s there was a common feeling among economists and political leaders that the goals and techniques of farm policy needed to be reexamined and revised. Moreover, crop prices were relatively high at the time and Congress wanted to reduce large federal budget deficits.

Freedom to Farm Act of 1996

In 1996 Congress radically revamped 60 years of U.S. farm policy by passing the **Freedom to Farm Act**. The law ended price supports and acreage allotments for wheat, corn, barley, oats, sorghum, rye, cotton, and rice. Farmers were allowed to respond to changing crop prices by planting as much or as little of these crops as they chose. Also, they were free to plant crops of their choice. If the price of, say, oats increased, farmers could plant more oats and less barley. Markets, not government programs, were to determine the kinds and amounts of crops grown.

To ease the transition away from price supports, the Freedom to Farm Act granted declining annual "transition payments" through 2002. \$37 billion of transition payments were scheduled through 2002 based on the production levels that had previously been imposed on farmers under the price-support

The Sugar Program: A Sweet Deal

The Sugar Program Is a Sweet Deal for Domestic Sugar Producers, but It Imposes Heavy Costs on Domestic Consumers, Domestic Candy Manufacturers, Foreign Producers, and the American Economy.

The continuing U.S. sugar program uses price supports and import quotas to guarantee a minimum price of sugar for domestic sugar producers. The program has significant effects, both domestically and internationally.

Domestic Costs Price supports and import quotas have boosted the domestic price of sugar to approximately 32 percent above the world price (for 2015, \$0.25 per pound compared to the international price of \$0.17 per pound). The aggregate cost to domestic consumers has been estimated at between \$1.5 billion and \$1.9 billion per year. In contrast, each sugar producer receives from subsidies alone an amount estimated to be twice the nation's average family income. In one particular year, a single producer received an estimated \$30 million in benefits. Many sugar

© Envision/Corbis

producers obtain more than \$1 million each year in benefits.

Import Quotas As a consequence of high U.S. domestic price supports, foreign sugar producers have a strong incentive to sell their output in the United States. But an influx of lower-priced foreign sugar into the U.S. domestic market would undermine U.S. price supports. The government therefore has imposed import quotas on foreign sugar. It decides how much sugar can be imported at a zero or very low tariff rate, and then it charges a prohibitively high tariff for any quantities above that amount. As the gap between U.S.-supported prices and world prices has widened, imports have declined as a percentage of sugar consumed

in the United States. In 1975, about 30 percent of the sugar consumed in the United States was imported; currently about 20 percent

system. A previous wheat farmer, for example, was scheduled to receive transition payments for 7 years regardless of the current price of wheat or the amount of wheat the farmer chose to grow over those 7 years.

This ambitious plan to wean American agriculture from subsidies unraveled in 1998 and 1999, when sharply reduced export demand and strong crop production in the United States depressed the prices of many farm products. Congress responded by supplementing the previously scheduled transition payments with large “emergency aid” payments to farmers. Agricultural subsidies for 1999–2002 averaged \$20 billion annually—even more than they were before passage of the Freedom to Farm Act.

The Food, Conservation, and Energy Act of 2008

Since 2002, agricultural policy in the United States has substantially retreated from the free-market intent of the Freedom to Farm Act of 1996. The three subsidy programs

introduced by the Food, Conservation, and Energy Act of 2008 continued the “freedom to plant” approach and provided revenue guarantees for farmers. But one of them transformed what were supposed to be temporary “transition payments” into “direct payments” that could be obtained year after year, without any time limit. These revenue guarantees kicked in automatically whenever crop prices (or total revenues) fell below target levels.

Direct Payments The **direct payments** under the 2008 law were similar to the transition payments paid under the Freedom to Farm Act. These cash payments were fixed for each crop based on a farmer's historical pattern of production and were unaffected by current crop prices or current production. Farmers could plant as much or as little of any particular crop as they wanted and still receive these payments. These direct payments did not decline from year to year. They were a permanent transfer payment from the federal government (general taxpayers) to farmers. The payments ranged from 2.4 cents per bushel for oats up to 54 cents per bushel for wheat.

comes from abroad. Domestic policy regarding the U.S. sugar industry largely dictates the nation's international trade policy with respect to sugar.

Developing Countries The loss of the U.S. market has had several harmful effects on sugar-exporting developing countries such as the Philippines, Brazil, and several Central American countries.

First, exclusion from the U.S. market has significantly reduced their export revenues—by an amount estimated to be many billions of dollars per year. That decline in export revenues is important because many of the sugar-producing countries depend on such revenues to pay interest and principal on large debts owed to the United States and other industrially advanced nations.

Second, barred by quotas from sale in the U.S. market, the sugar produced by the developing countries has been added to world markets, where the increased supply has depressed the world price of sugar.

Third, domestic price supports have caused U.S. sugar production to expand to the extent that the United States may soon change from a sugar-importing to a sugar-exporting nation. That is, the U.S. sugar program may soon be a source of new competition for the sugar producers of the developing countries. Sugar price supports in the European Union have already turned that group of nations into sugar exporters.

U.S. Efficiency Loss The sugar program benefits sugar producers by about \$1 billion annually but costs U.S. consumers about \$1.5

billion to \$1.9 billion each year. The excess of losses over gains is therefore \$500 million to \$900 million annually. This efficiency loss (or deadweight loss) results from the overallocation of U.S. resources to growing and processing sugar beets and sugar cane.

As a secondary effect, the higher domestic sugar prices have encouraged several U.S. confectionery firms (candy manufacturers) to relocate their operations to Canada or Mexico. According to the U.S. Commerce Department, for every American job that has been added by the price supports in the cane sugar and sugar beet industries, three American jobs have been lost in the industries buying sugar. Government economists estimate that the confectionery industry has lost a total of about 24,000 jobs since 2003.

Global Resource Misallocation Both domestically and globally, the sugar price-support programs of the United States and other industrially advanced economies have distorted the worldwide allocation of agricultural resources. Price supports have caused a shift of resources to sugar production by less efficient U.S. producers, and U.S. import quotas and consequent low world sugar prices have caused more-efficient foreign producers to restrict their production. Thus high-cost producers are producing more sugar and low-cost producers are producing less, resulting in the inefficient use of the world's agricultural resources.

Adding to the inefficient use of world resources, the relocation of candy manufacturers—to avoid artificially sweetened U.S. sugar prices—is moving capital and labor resources away from their place of comparative advantage.

Countercyclical Payments This component of 2008 farm policy tied a separate set of subsidies to the difference between market prices of specified farm products and a target price set for each crop. Like direct payments, these **countercyclical payments (CCPs)** were based on previous crops grown and were received regardless of the current crop planted. For example, the target price for corn in the years 2008–2012 was \$2.63 per bushel. If the price of corn stayed at or above \$2.63, the farmer who qualified would have received no CCP. But if the price fell below \$2.63, the farmer would have received a CCP payment geared to the size of the price gap. The CCP system returned a form of price supports to a prominent role in farm policy, but it based those supports on past crops grown, not current crops planted.

Marketing Loans The 2008 law contained a **marketing loan program** under which farmers could receive a loan (on a per-unit-of-output basis) from a government lender. If the crop price at harvest was higher than the price specified in the loan (the loan price), farmers had to repay their loans, with interest. If the crop price was lower than the loan price, farmers could

forfeit their harvested crops to the lender and be free of their loans. In this second case, farmers received what amounted to a subsidy because the proceeds from the loan exceeded the revenues from the sale of the crop in the market.

The Agricultural Act of 2014

The **Agricultural Act of 2014** ended both direct payments and countercyclical payments because it was politically difficult to justify paying farmers for crops they didn't grow. The marketing loan program was continued as a way for farmers to reduce the risk of price and revenue variability.

To help farmers further reduce risk, the Act created two new **crop insurance** programs:

- Under **price loss coverage**, farmers who elect to participate and pay the insurance premium are guaranteed an insurance payment if the price of their crop falls below a specified value, such as \$3.50 per bushel of wheat.
- By contrast, **agricultural risk coverage** depends on the total revenue generated by all of the farmers in a given

county who plant the same crop in a given year. The program makes insurance payments to participating farmers if the total revenue collectively received by all the farmers planting the crop in the county falls below a specific value, such as \$150 million for corn producers in Kossuth County, Iowa.

The 2014 Act also established the dairy margin protection program that makes payments if the price of milk falls too low or the cost of feed rises too high. The idea is to shield dairy producers' per-unit margin (= revenue per unit minus cost per unit).

The 2014 farm law reduced the risk of price and revenue variability for farmers and increased farm income. But the law failed to address the problem of subsidies. However structured, subsidies slow the exodus of resources from agriculture and maintain high production levels. This means lower crop prices and less market income for farmers. These lower prices and reduced market incomes, in turn, provide the rationale for continued government subsidies!

QUICK REVIEW 22.3

- ✓ Farm policy in the United States has been heavily criticized for delaying the shift of resources away from farming, directing most subsidies to wealthier farmers, and being fraught with policy contradictions.
- ✓ The persistence of farm subsidies can largely be explained in terms of rent-seeking behavior, the special-interest effect, political logrolling, and other aspects of public choice theory.
- ✓ The Freedom to Farm Act of 1996 eliminated price supports and acreage allotments for many of the nation's crops, while continuing direct subsidies to farmers.
- ✓ The Food, Conservation, and Energy Act of 2008 provided three major kinds of farm subsidies: direct payments, countercyclical payments, and marketing loans.
- ✓ The Agricultural Act of 2014 eliminated direct payments and countercyclical payments while introducing two types of crop insurance: price loss coverage and agricultural risk coverage.

SUMMARY

L022.1 Explain why agricultural prices and farm income are unstable.

In the short run, the highly inelastic demand for farm products transforms small changes in output and small shifts in demand into large changes in prices and income.

L022.2 Discuss why there has been a huge employment exodus from agriculture to other U.S. industries over the past several decades.

Over the long run, rapid technological advance, together with a highly inelastic and relatively slow-growing demand for agricultural output, has made agriculture a declining industry in the United States and dictated that resources exit the industry.

L022.3 Relate the rationale for farm subsidies and the economics and politics of price supports (price floors).

Historically, farm policy has been centered on price and based on the parity concept, which suggests that the relationship between prices received and paid by farmers should be constant over time.

The use of price floors or price supports has a number of economic effects: It (a) causes surplus production, (b) increases the incomes of farmers, (c) causes higher consumer prices for farm products, (d) creates an overallocation of resources to agriculture, (e) obliges society to pay higher taxes to finance the purchase and storage of surplus output, (f) increases pollution because of the greater use of agrochemicals and vulnerable land, and (g) forces other nations to bear the costs associated with import barriers and depressed world agricultural prices.

With only limited success, the federal government has pursued programs to reduce agricultural supply and increase agricultural demand as a way to reduce the surpluses associated with price supports.

L022.4 Describe major criticisms of the price-support system in agriculture.

Economists have criticized U.S. farm policy for (a) confusing symptoms (low farm incomes) with causes (excess capacity), (b) providing the largest subsidies to high-income farmers, and (c) creating contradictions among specific farm programs.

The persistence of agricultural subsidies can be explained by public choice theory and, in particular, as rent-seeking behavior, the special-interest effect, and political logrolling.

Political backing for price supports and acreage allotments has eroded for several reasons: (a) The number of U.S. farmers, and thus their political clout, has declined relative to the number of urban consumers of farm products, and (b) successful efforts by the United States to get other nations to reduce their farm subsidies have altered the domestic debate on the desirability of U.S. subsidies.

L022.5 List the main elements of existing federal farm policy.

The Freedom to Farm Act of 1996 ended price supports and acreage allotments for wheat, corn, barley, oats, sorghum, rye, cotton, and rice. The law established declining annual transition payments through the year 2002, but those payments were no longer tied to crop prices or the current crop produced.

When crop prices plummeted in 1998 and 1999, Congress supplemented the transition payments of the Freedom to Farm Act with large amounts of emergency aid. Total subsidies to agriculture averaged \$20 billion annually in the years 1999–2002.

Beginning in 2002, the federal government retreated from the free-market principles of the Freedom to Farm Act, setting up a system of permanent direct payments to farmers along with countercyclical farm-revenue guarantees.

The Food, Conservation, and Energy Act of 2008 provided farmers with direct payments (based on previous crops planted), countercyclical payments (based on the differences between market prices and targeted prices), and marketing loans (based on a specified crop price and an option to either pay back the loan or forfeit the crop to the government lender).

The Agricultural Act of 2014 preserved marketing loans but ended direct payments and countercyclical payments in favor of two types of crop insurance. Price loss coverage pays participating farmers if the market price of their crop falls below a predetermined value. Agricultural risk coverage pays out if the total revenue generated by a given crop in a given county falls below a preselected value.

DISCUSSION QUESTIONS

- Carefully evaluate: “The supply and demand for agricultural products are such that small changes in agricultural supply result in drastic changes in prices. However, large changes in agricultural prices have modest effects on agricultural output.” (Hint: A brief review of the distinction between *supply* and *quantity supplied* may be helpful.) Do exports increase or reduce the instability of demand for farm products? Explain. **L022.1**
- What relationship, if any, can you detect between the facts that farmers’ fixed costs of production are large and the supply of most agricultural products is generally inelastic? Be specific in your answer. **L022.1**
- Explain how each of the following contributes to the farm problem: **L022.1, L022.2**
 - The inelasticity of demand for farm products.
 - The rapid technological progress in farming.
 - The modest long-run growth in demand for farm commodities.
 - The volatility of export demand.
- The key to efficient resource allocation is shifting resources from low-productivity to high-productivity uses. In view of the high and expanding physical productivity of agricultural resources, explain why many economists want to divert additional resources away from farming in order to achieve allocative efficiency. **L022.2**
- Explain and evaluate: “Industry complains of the higher taxes it must pay to finance subsidies to agriculture. Yet the trend of agricultural prices has been downward, while industrial prices have been moving upward, suggesting that on balance agriculture is actually subsidizing industry.” **L022.3**
- “Because consumers as a group must ultimately pay the total income received by farmers, it makes no real difference whether the income is paid through free farm markets or through price supports supplemented by subsidies financed out of tax revenue.” Do you agree? **L022.3**
- If in a given year the indexes of prices received and paid by farmers were 120 and 165, respectively, what would the parity ratio be? Explain the meaning of that ratio. **L022.3**
- Explain the economic effects of price supports. Explicitly include environmental and global impacts in your answer. On what grounds do economists contend that price supports cause a misallocation of resources? **L022.3**
- Do you agree with each of the following statements? Explain why or why not. **L022.3, L022.4**
 - The problem with U.S. agriculture is that there are too many farmers. That is not the fault of farmers but the fault of government programs.
 - The federal government ought to buy up all U.S. farm surpluses and give them away to developing nations.
 - All industries would like government price supports if they could get them; agriculture has obtained price supports only because of its strong political clout.
- What are the effects of farm subsidies such as those of the United States and the European Union on (a) domestic agricultural prices, (b) world agricultural prices, and (c) the international allocation of agricultural resources? **L022.3**
- Use public choice theory to explain the persistence of farm subsidies in the face of major criticisms of those subsidies. If the special-interest effect is so strong, what factors made it possible in 1996 for the government to end price supports and acreage allotments for several crops? **L022.4**
- What was the major intent of the Freedom to Farm Act of 1996? Do you agree with the intent? Why or why not? Did the law succeed in reducing overall farm subsidies? Why or why not? **L022.5**
- Distinguish between price loss coverage and agricultural risk coverage. How do they help reduce the volatility of farm income? In what way do farm subsidies perpetuate the long-standing problem of too many resources in agriculture? **L022.5**
- LAST WORD** What groups benefit and what groups lose from the U.S. sugar subsidy program?

REVIEW QUESTIONS

- Suppose that the demand for olive oil is highly inelastic. Also suppose that the supply of olive oil is fixed for the year. If the demand for olive oil suddenly increases because of a shortage of corn oil, you would expect a _____ in the price of olive oil. **LO22.2**
 - Large increase.
 - Small increase.
 - Large decrease.
 - Small decrease.
 - No change.
- Use supply and demand curves to depict equilibrium price and output in a competitive market for some farm product. Then show how an above-equilibrium price floor (price support) would cause a surplus in this market. Demonstrate in your graph how government could reduce the surplus through a policy that (a) changes supply or (b) changes demand. Identify each of the following actual government policies as primarily affecting the supply of or the demand for a particular farm product: acreage allotments, the food-stamp program, the Food for Peace program, a government buyout of dairy herds, and export promotion. **LO22.3**
- Suppose that the government has been supporting the price of corn. Its free market price is \$2.50 per bushel, but the government has been setting a support price of \$3.50 per bushel. Which of the following are ways that the government might try to reduce the size of the corn surplus? (Select one or more answers from the choices shown.) **LO22.3**
 - Decrease the support price.
 - Institute an acreage allotment program.
 - Decrease demand by taxing purchases of corn.
 - Raise the support price.
- The majority of farm subsidies flow toward _____. **LO22.4**
 - Poor, small-scale farmers.
 - Rich, large-scale farmers.
 - Government employees.
 - Grain wholesalers.
- Which of the following are elements of current U.S. farm policy? **LO22.5**
 - Farmers are free to choose how much to plant of any particular crop.
 - Direct payments.
 - Price supports.
 - Countercyclical payments.

PROBLEMS

- Suppose that corn currently costs \$4 per bushel and that wheat currently costs \$3 per bushel. Also assume that the price elasticity of corn is 0.10, while the price elasticity of wheat is 0.15. For the following questions about elasticities, simply use the percentage changes that are provided rather than attempting to calculate those percentage changes yourself using the midpoint formula given in Chapter 6. **LO22.1**
 - If the price of corn fell by 25 percent to \$3 per bushel, by what percentage would the quantity demanded of corn increase? What if the price of corn fell by 50 percent to \$2 per bushel?
 - To what value would the price of wheat have to fall to induce consumers to increase their purchases of wheat by 5 percent?
 - If the government imposes a \$0.40 per bushel tax on corn so that the price of corn rises by 10 percent to \$4.40 per bushel, by what percentage would the quantity demanded of corn decrease? If the initial quantity demanded is 10 billion bushels per year, by how many bushels would the quantity demanded decrease in response to this tax?
- Suppose that both wheat and corn have an income elasticity of 0.1. **LO22.1**
 - If the average income in the economy increases by 2 percent each year, by what percentage does the quantity demanded of wheat increase each year, holding all other factors constant? Holding all other factors constant, if 10 billion bushels are demanded this year, by how many bushels will the quantity demanded increase next year if incomes rise by 2 percent?
 - Given that average personal income doubles in the United States about every 30 years, by about what percentage does the quantity demanded of corn increase every 30 years, holding all other factors constant?
- Suppose that 10 workers were required in 2010 to produce 40,000 bushels of wheat on a 1,000-acre farm. **LO22.2**
 - What is the average output per acre? Per worker?
 - If in 2020 only 8 workers produce 44,000 bushels of wheat on that same 1,000-acre farm, what will be the average output per acre? Per worker?
 - By what percentage does productivity (output per worker) increase over those 10 years? Over those 10 years, what is the average annual percentage increase in productivity?
- In 2013, it was estimated that the total value of all corn-production subsidies in the United States totaled about \$4.8 billion. The population of the United States was approximately 315 million people that year. **LO22.3**
 - On average, how much did corn subsidies cost per person in the United States in 2013? (Hint: A billion is a 1 followed by nine zeros. A million is a 1 followed by six zeros.)
 - If each person in the United States is only willing to spend \$0.50 to support efforts to overturn the corn subsidy, and if antisubsidy advocates can only raise funds from 10 percent of the population, how much money will they be able to raise for their lobbying efforts?
 - If the recipients of corn subsidies donate just 1 percent of the total amount that they receive in subsidies, how much could they raise to support lobbying efforts to continue the corn subsidy?
 - By how many dollars does the amount raised by the recipients of the corn subsidy exceed the amount raised by the opponents of the corn subsidy?

Income Inequality, Poverty, and Discrimination

Learning Objectives

- LO23.1** Explain how income inequality in the United States is measured and described.
- LO23.2** Discuss the extent and sources of income inequality.
- LO23.3** Demonstrate how income inequality has changed since 1975.
- LO23.4** Debate the economic arguments for and against income inequality.
- LO23.5** Relate how poverty is measured and its incidence by age, gender, ethnicity, and other characteristics.
- LO23.6** Identify the major components of the income-maintenance program in the United States.
- LO23.7** Discuss labor market discrimination and how it might affect hiring decisions and wages.

Evidence that suggests wide income disparity in the United States is easy to find. In 2015 boxer Floyd Mayweather earned \$300 million, singer Katy Perry earned \$135 million, and celebrity chef Gordon Ramsay earned \$60 million. In contrast, the salary of the president of the United States is \$400,000, and the typical schoolteacher earns \$56,000. A full-time minimum-wage worker at a fast-food restaurant makes about \$15,000. Cash welfare payments to a mother with two children average \$5,150 per year.

In 2014 about 46.7 million Americans—or 15.0 percent of the population—lived in poverty. An estimated 576,400 people were homeless that year. The richest fifth of American households received about 51.2 percent of total income, while the poorest fifth received about 3.1 percent.

What are the sources of income inequality? Is income inequality rising or falling? Is the United States making progress against poverty? What are the major income-maintenance programs in the United States? What role does discrimination play in reducing wages for some and increasing wages for others? These are some of the questions we will answer in this chapter.

Facts about Income Inequality

LO23.1 Explain how income inequality in the United States is measured and described.

Average household income in the United States is among the highest in the world; in 2014, it was \$68,426 per household (one or more persons occupying a housing unit). But that average tells us nothing about income inequality. To learn about that, we must examine how income is distributed around the average.

Distribution by Income Category

One way to measure **income inequality** is to look at the percentages of households in a series of income categories. Table 23.1 shows that 23.6 percent of all households had annual before-tax incomes of less than \$25,000 in 2014, while 24.7 percent had annual incomes of \$100,000 or more. The data in the table suggest a wide dispersion of household income and considerable inequality of income in the United States.

Distribution by Quintiles (Fifths)

A second way to measure income inequality is to divide the total number of individuals, households, or families (two or more persons related by birth, marriage, or adoption) into five numerically equal groups, or *quintiles*, and examine the percentage of total personal (before-tax) income received by each quintile. We do this for households in the table in Figure 23.1, where we also provide the upper income limit for each quintile. Any amount of income greater than that listed in each row of column 3 would place a household into the next-higher quintile.

TABLE 23.1 The Distribution of U.S. Income by Households, 2014

(1) Personal Income Category	(2) Percentage of All Households in This Category

\$15,000–\$24,999	11.0
\$25,000–\$34,999	10.1

The Lorenz Curve and Gini Ratio

We can display the quintile distribution of personal income through a **Lorenz curve**. In Figure 23.1, we plot the cumulative percentage of households on the horizontal axis and the percentage of income they obtain on the vertical axis. The diagonal line *Oe* represents a *perfectly equal distribution of income* because each point along that line indicates that a particular percentage of households receive the same percentage of income. In other words, points representing 20 percent of all households receiving 20 percent of total income, 40 percent receiving 40 percent, 60 percent receiving 60 percent, and so on, all lie on the diagonal line.

By plotting the quintile data from the table in Figure 23.1, we obtain the Lorenz curve for 2014. The bottom 20 percent of all households received 3.1 percent of the income, as shown by point *a*; the bottom 40 percent received 11.3 percent (= 3.1 + 8.2), as shown by point *b*; and so forth. The blue area between the diagonal line and the Lorenz curve is determined by the extent that the Lorenz curve sags away from the diagonal and indicates the degree of income inequality. If the actual income distribution were perfectly equal, the Lorenz curve and the diagonal would coincide and the blue area would disappear.

At the opposite extreme is complete inequality, where all households but one have zero income. In that case the Lorenz curve would coincide with the horizontal axis from 0 to point *f* (at 0 percent of income) and then would move immediately up from *f* to point *e* along the vertical axis (indicating that a single household has 100 percent of the total income). The entire area below the diagonal line (triangle *Oef*) would indicate this extreme degree of inequality. So the farther the Lorenz curve sags away from the diagonal, the greater is the degree of income inequality.

The income inequality described by the Lorenz curve can be transformed into a **Gini ratio**—a numerical measure of the overall dispersion of income:

$$\begin{aligned} \text{Gini ratio} &= \frac{\text{Area between Lorenz curve and diagonal}}{\text{Total area below the diagonal}} \\ &= \frac{A \text{ (blue area)}}{A + B \text{ (blue + green area)}} \end{aligned}$$

The Gini ratio is 0.480 for the distribution of household income shown in Figure 23.1. As the area between the Lorenz curve and the diagonal gets larger, the Gini ratio rises to reflect greater inequality. Lower Gini ratios denote less inequality; higher ratios indicate more inequality. The Gini coefficient for complete income equality is zero and for complete inequality is 1.

Because Gini ratios are numerical, they are easier to use than Lorenz curves for comparing the income distributions of

FIGURE 23.1 The Lorenz curve and Gini ratio. The Lorenz curve is a convenient way to show the degree of income inequality (here, household income by quintile in 2014). The area between the diagonal (the line of perfect equality) and the Lorenz curve represents the degree of inequality in the distribution of total income. This inequality is measured numerically by the Gini ratio—area *A* (shown in blue) divided by area *A* + *B* (the blue + green area). The Gini ratio for the distribution shown is 0.480.

different ethnic groups and countries. For example, in 2014 the Gini ratio of U.S. household income for Hispanics was 0.455; for whites, 0.472; for Asians, 0.463; and for African-Americans, 0.499.¹ In 2014, national Gini ratios ranged from a low of 0.247 in Ukraine to a high of 0.608 in Haiti. Examples within this range include Denmark, 0.291; Italy, 0.352; Mexico, 0.481; and Honduras, 0.574.²

Income Mobility: The Time Dimension

The income data used so far have a major limitation: The income accounting period of 1 year is too short to be very meaningful. Because the Census Bureau data portray the distribution of income in only a single year, they may conceal a more equal distribution over a few years, a decade, or even a lifetime. If Brad earns \$1,000 in year 1 and \$100,000 in year 2, while Jenny earns \$100,000 in year 1 and only \$1,000 in year 2, do we have income inequality? The answer depends on the period of measurement. Annual data would reveal great income inequality, but there would be complete equality over the 2-year period.

This point is important because evidence suggests considerable “churning around” in the distribution of income over time. Such movement of individuals or households from one

income quintile to another over time is called **income mobility**. For most income receivers, income starts at a relatively low level during youth, reaches a peak during middle age, and then declines. It follows that if all people receive exactly the same stream of income over their lifetimes, considerable income inequality would still exist in any specific year because of age differences. In any single year, the young and the old would receive low incomes while the middle-aged receive high incomes.

If we change from a “snapshot” view of income distribution in a single year to a “time exposure” portraying incomes over much longer periods, we find considerable movement of income receivers among income classes. For instance, one study showed that between 1996 and 2005, half the individuals in the lowest quintile of the U.S. income distribution in 1996 were in a higher income quintile in 2005. Almost 25 percent made it to the middle fifth and 5 percent achieved the top quintile. There was income mobility in both directions. About 57 percent of the top 1 percent of income receivers in 1996 had dropped out of that category by 2005. Overall, income mobility between 1996 and 2005 was the same as it was the previous 10 years. All this correctly suggests that income is more equally distributed over a 5-, 10-, or 20-year period than in any single year.³

Income received “after taxes and transfers” includes both cash and noncash transfers as well as realized capital gains and employer-provided health insurance. Numbers may not add to 100 percent due to rounding.

In short, individual and family income mobility over time is significant; for many people, “low income” and “high income” are not permanent conditions. Also, the longer the time period considered, the more equal the distribution of income becomes.

Effect of Government Redistribution

The income data in Table 23.1 and Figure 23.1 include wages, salaries, dividends, and interest. They also include all cash transfer payments such as Social Security, unemployment compensation benefits, and welfare assistance to needy families. The data are before-tax data and therefore do not take into account the effects of personal income and payroll (Social Security) taxes that are levied directly on income receivers. Nor do they include in-kind or **noncash transfers**, which provide specific goods or services rather than cash. Noncash transfers include such things as Medicare, Medicaid, housing subsidies, subsidized school lunches, and food stamps. Such transfers are “incomelike,” since they enable recipients to “purchase” goods and services.

One economic function of government is to redistribute income, if society so desires. Figure 23.2 and its table⁴ reveal that government significantly redistributes income from higher- to lower-income households through taxes and transfers. Note that the U.S. distribution of household income before taxes and transfers are taken into account (dark red Lorenz curve) is

substantially less equal than the distribution after taxes and transfers (light red Lorenz curve). Without government redistribution, the lowest 20 percent of households in 2013 would have received only 2.2 percent of total income. *With* redistribution, they received 9.3 percent, or 4.2 times as much.

Which contributes more to redistribution, government taxes or government transfers? The answer is transfers. As discussed in Chapter 20’s Last Word, the combined federal, state, and local tax system in the United States is only modestly progressive. As a result, nearly all the reduction in income inequality in the United States is attributable to transfer payments. Together with job opportunities, transfer payments have been the most important means of alleviating poverty in the United States.

Causes of Income Inequality

L023.2 Discuss the extent and sources of income inequality. There are several causes of income inequality in the United States. In general, the market system is permissive of a high degree of income inequality because it rewards individuals based on the contributions that they make, or the resources that they own, in producing society’s output.

More specifically, the factors that contribute to income inequality are the following.

Ability

People have different mental, physical, and aesthetic talents. Some have inherited the exceptional mental qualities that are essential to such high-paying occupations as medicine, corporate leadership, and law. Others are blessed with the physical capacity and coordination to become highly paid

⁴The “before” data in this table differ from the data in the table in Figure 23.1 because the latter include cash transfers. Also, the data in Figure 23.2 are based on a broader concept of income than are the data in Figure 23.1.

professional athletes. A few have the talent to become great artists or musicians or have the beauty to become top fashion models. Others have very weak mental endowments and may work in low-paying occupations or may be incapable of earning any income at all. The intelligence and skills of most people fall somewhere in between.

Education and Training

Native ability alone rarely produces high income; people must develop and refine their capabilities through education and training. Individuals differ significantly in the amount of education and training they obtain and thus in their capacity to earn income. Such differences may be a matter of choice: Nguyen enters the labor force after graduating from high school, while Nyberg takes a job only after earning a college degree. Other differences may be involuntary: Nguyen and her parents may simply be unable to finance a college education.

People also receive varying degrees of on-the-job training, which contributes to income inequality. Some workers learn valuable new skills each year on the job and therefore experience significant income growth over time; others receive little or no on-the-job training and earn no more at age 50 than they did at age 30. Moreover, firms tend to select for advanced on-the-job training the workers who have the most formal education. That added training magnifies the education-based income differences between less-educated and better-educated individuals.

Discrimination

Discrimination in education, hiring, training, and promotion undoubtedly causes some income inequality. If discrimination confines certain racial, ethnic, or gender groups to lower-pay occupations, the supply of labor in those occupations will increase relative to demand, and hourly wages and income in those lower-pay jobs will decline. Conversely, labor supply will be artificially reduced in the higher-pay occupations populated by “preferred” workers, raising their wage rates and income. In this way, discrimination can add to income inequality. In fact, economists cannot account for all racial, ethnic, and gender differences in work earnings on the basis of differences in years of education, quality of education, occupations, and annual hours of work. Many economists attribute the unexplained residual to discrimination.

Economists, however, do not see discrimination by race, gender, and ethnicity as a dominant factor explaining income inequality. The income distributions *within* racial or ethnic groups that historically have been targets of discrimination—for example, African Americans—are similar to the income distribution for whites. Other factors besides discrimination are obviously at work.

Nevertheless, discrimination is an important concern since it harms individuals and reduces society’s overall

output and income. We will discuss it in more detail later in this chapter.

Preferences and Risks

Incomes also differ because of differences in preferences for market work relative to leisure, market work relative to work in the household, and types of occupations. People who choose to stay home with children, work part-time, or retire early usually have less income than those who make the opposite choices. Those who are willing to take arduous, unpleasant jobs (for example, underground mining or heavy construction), to work long hours with great intensity, or to “moonlight” will tend to earn more.

Individuals also differ in their willingness to assume risk. We refer here not only to the race-car driver or the professional boxer but also to the entrepreneur. Although many entrepreneurs fail, many of those who develop successful new products or services realize very substantial incomes. That contributes to income inequality.

Unequal Distribution of Wealth

Income is a *flow*; it represents a stream of wage and salary earnings, along with rent, interest, and profits, as depicted in Chapter 2’s circular flow diagram. In contrast, wealth is a *stock*, reflecting at a particular moment the financial and real assets an individual has accumulated over time. A retired person may have very little income and yet own a home, mutual fund shares, and a pension plan that add up to considerable wealth. A new college graduate may be earning a substantial income as an accountant, middle manager, or engineer but has yet to accumulate significant wealth.

As you will discover in this chapter’s Last Word, the ownership of wealth in the United States is more unequal than the distribution of income. This inequality of wealth leads to inequality in rent, interest, and dividends, which in turn contributes to income inequality. Those who own more machinery, real estate, farmland, stocks, and bonds and who have more money in savings accounts obviously receive greater income from that ownership than people with less or no such wealth.

Market Power

The ability to “rig the market” on one’s own behalf also contributes to income inequality. For example, in *resource* markets certain unions and professional groups have adopted policies that limit the supply of their services, thereby boosting the incomes of those “on the inside.” Also, legislation that requires occupational licensing for, say, doctors, dentists, and lawyers can bestow market power that favors the licensed groups. In *product* markets, “rigging the market” means gaining or enhancing monopoly power, which results in greater profit and thus greater income to the firms’ owners.

Luck, Connections, and Misfortune

Other forces also play a role in producing income inequality. Luck and “being in the right place at the right time” have helped individuals stumble into fortunes. Discovering oil on a ranch, owning land along a proposed freeway interchange, and hiring the right press agent have accounted for some high incomes. Personal contacts and political connections are other potential routes to attaining high income.

In contrast, economic misfortunes such as prolonged illness, serious accident, the death of the family breadwinner, or unemployment may plunge a family into the low range of income. The burden of such misfortune is borne very unevenly by the population and thus contributes to income inequality.

Income inequality of the magnitude we have described is not exclusively an American phenomenon. Global Perspective 23.1 compares income inequality (here by individuals, not by households) in the United States with that in several other nations. Income inequality tends to be greatest in South American nations, where land and capital resources are highly concentrated in the hands of a relatively small number of wealthy families.

QUICK REVIEW 23.1

- ✓ Data reveal considerable income inequality in the United States; in 2014 the richest fifth of all households received 51.2 percent of before-tax income, and the poorest fifth received 3.1 percent.
- ✓ The Lorenz curve depicts income inequality graphically by comparing percentages of total families and percentages of total income. The Gini ratio is a measure of the overall dispersion of income and is found by dividing the area between the diagonal and the Lorenz curve by the total area below the diagonal.
- ✓ The distribution of income is less unequal over longer time periods.
- ✓ Government taxes and transfers significantly reduce income inequality by redistributing income from higher-income groups to lower-income groups; the bulk of this redistribution results from transfer payments.
- ✓ Differences in ability, education and training, preferences for market work versus nonmarket activities, property ownership, and market power—along with discrimination and luck—help explain income inequality.

Income Inequality over Time

L023.3 Demonstrate how income inequality has changed since 1975.

Over a period of years economic growth has raised incomes in the United States: In *absolute* dollar amounts, the entire distribution of income has been moving upward. But incomes may move up in *absolute* terms while leaving the *relative* distribution of income less equal, more equal, or unchanged. Table 23.2 shows how the distribution of household income has changed since 1975. This income is “before tax” and includes cash transfers but not noncash transfers.

Rising Income Inequality since 1975

It is clear from Table 23.2 that the distribution of income by quintiles has become more unequal since 1975. In 2014 the lowest 20 percent of households received 3.1 percent of total before-tax income, compared with 4.4 percent in 1975. Meanwhile, the income share received by the highest 20 percent rose from 43.2 in 1975 to 51.2 percent in 2014. The percentage of income received by the top 5 percent of households also rose significantly over the 1975–2014 period.

Causes of Growing Inequality

Economists suggest several major explanations for the increase in U.S. income inequality since 1975.

Greater Demand for Highly Skilled Workers Perhaps the most significant contributor to the growing income inequality has been an increasing demand by many firms for workers who are highly skilled and well-educated. Moreover, several industries requiring highly skilled workers have either recently emerged or expanded greatly, such as the computer software, business consulting, biotechnology, health care, and Internet industries. Because highly skilled workers remain relatively scarce, their wages have been bid up. Consequently, the wage differences between them and less-skilled workers have increased.

Between 1980 and 2007 the wage difference between college graduates and high school graduates rose from 28 percent to 49 percent for women and from 22 percent to 44 percent for men. And the so-called *90-10 ratio*—how many times larger the hourly wage at the 90th percentile is compared to the hourly wage at the 10th percentile—rose from 3.6 in 1980 to 4.5 in 2007.⁵

The rising demand for skill has also shown up in rapidly rising pay for chief executive officers (CEOs), sizable increases in income from stock options, substantial increases in income for professional athletes and entertainers, and huge fortunes for successful entrepreneurs. This growth of “super-star” pay has also contributed to rising income inequality.

Demographic Changes The entrance of large numbers of less-experienced and less-skilled “baby boomers” into the labor force during the 1970s and 1980s may have contributed to greater income inequality in those two decades.

⁵Economic Policy Institute, www.epinet.org. The college wage premiums are adjusted for differences in earnings based on race, ethnicity, marital status, and region.

Because younger workers tend to earn less income than older workers, their growing numbers contributed to income inequality. There has also been a growing tendency for men and women with high earnings potential to marry each other, thus increasing household income among the highest income quintiles. Finally, the number of households headed by single or divorced women has increased greatly. That trend has increased income inequality because such households lack a second major wage earner and also because the poverty rate for female-headed households is very high.

International Trade, Immigration, and Decline in Unionism Other factors are probably at work as well. Stronger international competition from imports has reduced the demand for and employment of less-skilled (but highly paid) workers in such industries as the automobile and steel industries. The decline in such jobs has reduced the average wage for less-skilled workers. It also has swelled the ranks of workers in already low-paying industries, placing further downward pressure on wages there.

Similarly, the transfer of jobs to lower-wage workers in developing countries has exerted downward wage pressure on less-skilled workers in the United States. Also, an upsurge in the immigration of unskilled workers has increased the number of low-income households in the United States. Finally, the decline in unionism in the United States has undoubtedly contributed to wage inequality, since unions tend to equalize pay within firms and industries.

Two cautions: First, when we note growing income inequality, we are not saying that the “rich are getting richer and the poor are getting poorer” in terms of absolute income. Both the rich and the poor are experiencing rises in real income. Rather, what has happened is that, while incomes have risen in all quintiles, income growth has been fastest in the top quintile. Second, increased income inequality is not solely a U.S. phenomenon. The recent rise of inequality has also occurred in several other industrially advanced nations.

Laughing at The Lego Movie

Some economists say that the distribution of annual *consumption* is more

meaningful for examining inequality of well-being than is the distribution of annual *income*. In a given year, people's consumption of goods and services may be above or below their income because they can save, draw down past savings, use credit cards, take out home mortgages, spend from inheritances, give money to charities, and so on.

A recent study of the distribution of consumption finds that annual consumption inequality is less than income inequality. Moreover, consumption inequality has remained relatively constant over several decades, even though income inequality has increased.*

The Economist magazine extends the argument even further, pointing out that despite the recent increase in income inequality, the products consumed by the rich and the poor are far closer in functionality today than at any other time in history.

More than 70 percent of Americans under the official poverty line own at least one car. The difference between driving a beat-up sedan and a high-end sports car is nigh undetectable when compared to the difference between driving and hiking through the mud. A flat panel television is lovely, but you do not need one to laugh at *The Lego Movie*.

The successful entrepreneurs who make fortunes by improving quality while dropping prices widen the income gap while reducing meaningful differences.†

Economists generally agree that products and experiences once reserved exclusively for the rich in the United States have, in fact, become more commonplace for nearly all income classes. But skeptics contend that *The Economist's* argument is too simplistic. Even though both are water outings, there is a fundamental difference between sailing among the Greek isles on your private yacht and paddling on a local pond in a rented kayak.

The Lorenz curve can be used to contrast the distribution of income at different points in time. If we plotted Table 23.2's data as Lorenz curves, we would find that the curves shifted farther away from the diagonal between 1975 and 2014. The Gini ratio rose from 0.397 in 1975 to 0.480 in 2014.

Equality versus Efficiency

L023.4 Debate the economic arguments for and against income inequality.

The main policy issue concerning income inequality is how much is necessary and justified. While there is no general agreement on the justifiable amount, we can gain insight by exploring the cases for and against greater equality.

The Case for Equality: Maximizing Total Utility

The basic argument for an equal distribution of income is that income equality maximizes total consumer satisfaction (utility) from any particular level of output and income. The rationale for this argument is shown in Figure 23.3, in which we assume that the money incomes of two individuals, Anderson and Brooks, are subject to diminishing marginal utility. In any time period, income receivers spend the first dollars received on the products they value most—products whose marginal utility is high. As their most pressing wants become satisfied, consumers then spend additional dollars of income on less-important, lower-marginal-utility goods. The identical diminishing-marginal-utility-from-income curves (MU_A and MU_B in the figure) reflect the assumption that Anderson and Brooks have the same capacity to derive utility from income.

Now suppose that there is \$10,000 worth of income (output) to be distributed between Anderson and Brooks. According to proponents of income equality, the optimal distribution is an equal distribution, which causes the marginal utility of the last dollar spent to be the same for both persons. We can prove this by demonstrating that if the income distribution is initially unequal, then distributing income more equally can increase the combined utility of the two individuals.

Suppose that the \$10,000 of income initially is distributed unequally, with Anderson getting \$2,500 and Brooks \$7,500. The marginal utility, a , from the last dollar received by Anderson is high, and the marginal utility, b , from Brooks's last dollar of income is low. If a single dollar of income is shifted from Brooks to Anderson—that is, toward greater equality—then Anderson's utility increases by a and Brooks's utility decreases by b . The combined utility then increases by a minus b (Anderson's large gain minus Brooks's small loss). The transfer of another dollar from Brooks to Anderson again increases their combined utility, this time by a slightly smaller amount. Continued transfer of dollars from Brooks to Anderson increases their combined utility until the income is evenly distributed and both receive \$5,000. At that time their marginal utilities from the last dollar of income are equal (at a' and b'), and any further income redistribution beyond the \$2,500 already transferred would begin to create inequality and decrease their combined utility.

FIGURE 23.3 The utility-maximizing distribution of income. With identical marginal-utility-of-income curves MU_A and MU_B , Anderson and Brooks will maximize their combined utility when any amount of income (say, \$10,000) is equally distributed. If income is unequally distributed (say, \$2,500 to Anderson and \$7,500 to Brooks), the marginal utility derived from the last dollar will be greater for Anderson than for Brooks, and a redistribution of income toward equality will result in a net increase in total utility. The utility gained by equalizing income at \$5,000 each, shown by the blue area below curve MU_A in panel (a), exceeds the utility lost, indicated by the red area below curve MU_B in (b).

The area under the MU curve and to the left of the individual's particular level of income represents the total utility of that income. Therefore, as a result of the transfer of the \$2,500, Anderson has gained utility represented by the blue area below curve MU_A , and Brooks has lost utility represented by the red area below curve MU_B . The blue area is obviously greater than the red area, so income equality yields greater combined total utility than income inequality does.

The Case for Inequality: Incentives and Efficiency

Although the logic of the argument for equality might seem solid, critics of income equality say that the transfer of income required to create income equality is both unfair and unwise. They say that income inequality largely reflects rewards to individuals for supplying their talents and resources to the economy. They conclude that it is not fair to take some of Brooks's income and give it to Anderson. Further, critics of income equality point out that proponents of income equality falsely assume that there is some fixed amount of output produced and therefore income to be distributed. These critics argue that the way in which income is distributed is an important determinant of the amount of output or income that is produced and is available for distribution.

Suppose once again in Figure 23.3 that Anderson earns \$2,500 and Brooks earns \$7,500. In moving toward equality, society (the government) must tax away some of Brooks's income and transfer it to Anderson. This tax and transfer process diminishes the income rewards of high-income Brooks and raises the income rewards of low-income Anderson; in so doing, it reduces the incentives of both to earn high incomes. Why should high-income Brooks work hard, save and invest, or undertake entrepreneurial risks when the rewards from such activities will be reduced by taxation? And why should low-income Anderson be motivated to increase his income through market activities when the government stands ready to transfer income to him? Taxes are a reduction in the rewards from increased productive effort; redistribution through transfers is a reward for diminished effort.

In the extreme, imagine a situation in which the government levies a 100 percent tax on income and distributes the tax revenue equally to its citizenry. Why would anyone work hard? Why would anyone work at all? Why would anyone assume business risk? Or why would anyone save (forgo current consumption) in order to invest? The economic incentives to "get ahead" will have been removed, greatly reducing society's total production and income. That is, the way income is distributed affects the size of that income. The basic argument for income inequality therefore is twofold: (1) income inequality is justified because it results from differences in

Slicing the Pizza

The equality-efficiency trade-off might better be understood through an analogy. Assume that society's income is a huge pizza, baked year after year,

with the sizes of the pieces going to people on the basis of their contribution to making it. Now suppose that for fairness reasons, society decides some people are getting pieces that are too large and others are getting pieces too small. But when society redistributes the pizza to make the sizes more equal, they discover the result is a smaller pizza than before. Why participate in making the pizza if you get a decent-size piece without contributing? The shrinkage of the pizza represents the efficiency loss—the loss of output and income—caused by the harmful effects of the redistribution on incentives to work, to save and invest, and to accept entrepreneurial risk. The shrinkage also reflects the resources that society must divert to the bureaucracies that administer the redistribution system.

How much pizza shrinkage will society accept while continuing to agree to the redistribution? If redistributing pizza to make it less unequal reduces the size of the pizza, what amount of pizza loss will society tolerate? Is a loss of 10 percent acceptable? 25 percent? 75 percent? This is the basic question in any debate over the ideal size of a nation's income redistribution program.

the quantity and quality of labor and other resources supplied by individuals to the economy, and (2) it is an unavoidable consequence of maintaining the incentives needed to motivate people to produce output and income year after year.

The Equality-Efficiency Trade-off

At the essence of the income equality-inequality debate is a fundamental trade-off between equality and efficiency. In this **equality-efficiency trade-off**, greater income equality (achieved through redistribution of income) comes at the opportunity cost of reduced production and income. And greater production and income (through reduced redistribution) comes at the expense of less equality of income. The trade-off obligates society to choose how much redistribution it wants, in view of the costs. If society decides it wants to redistribute income, it needs to determine methods that

minimize the adverse effects on fairness, incentives, productivity, and economic efficiency.

The Economics of Poverty

L023.5 Relate how poverty is measured and its incidence by age, gender, ethnicity, and other characteristics.

We now turn from the broader issue of income distribution to the more specific issue of very low income, or “poverty.” A society with a high degree of income inequality can have a high, moderate, or low amount of poverty. We therefore need a separate examination of poverty.

Definition of Poverty

Poverty is a condition in which a person or a family does not have the means to satisfy basic needs for food, clothing, shelter, and transportation. The means include currently earned income, transfer payments, past savings, and property owned. The basic needs have many determinants, including family size and the health and age of its members.

The federal government has established minimum income thresholds below which a person or a family is “in poverty.” In 2014 an unattached individual receiving less than \$12,071 per year was said to be living in poverty. For a family of four, the poverty line was \$24,230; for a family of six, it was \$32,473. Based on these thresholds, in 2014 about 46.7 million Americans lived in poverty. In 2014 the **poverty rate**—the percentage of the population living in poverty—was 14.8 percent.

Incidence of Poverty

The poor are heterogeneous: They can be found in all parts of the nation; they are of all races and ethnicities, rural and urban, young and old. But as Figure 23.4 indicates, poverty is far from randomly distributed. For example, the poverty rate for African Americans is above the national average, as is the rate for Hispanics, while the rates for whites and Asians are below the average. In 2014, the poverty rates for African Americans and Hispanics were 25.2 and 23.6, respectively; for whites and Asians, 12.9 and 13.1 percent, respectively.⁶

Figure 23.4 shows that female-headed households (no husband present), foreign-born noncitizens, and children under 18 years of age have very high incidences of poverty. Marriage and full-time, year-round work are associated with low poverty rates, and, because of the Social Security system, the incidence of poverty among the elderly is less than that for the population as a whole.

The high poverty rate for children is especially disturbing because poverty tends to breed poverty. Poor children are at greater risk for a range of long-term problems, including poor health and inadequate education, crime, drug use, and teenage pregnancy. Many of today's impoverished children will

FIGURE 23.4 Poverty rates among selected population groups, 2014. Poverty is disproportionately borne by African Americans, Hispanics, children, foreign-born residents who are not citizens, and families headed by women. People who are employed full-time, have a college degree, or are married tend to have low poverty rates.

reach adulthood unhealthy and illiterate and unable to earn above-poverty incomes.

As many as half of people in poverty are poor for only one or two years before climbing out of poverty. But poverty is much more long-lasting among some groups than among others. In particular, African American and Hispanic families, families headed by women, persons with little education and few labor market skills, and people who are dysfunctional because of drug use, alcoholism, or mental illness are more likely than others to remain in poverty. Also, long-lasting poverty is heavily present in depressed areas of cities, parts of the Deep South, and some Indian reservations.

Poverty Trends

As Figure 23.5 shows, the total poverty rate fell significantly between 1959 and 1969, stabilized at 11 to 13 percent over the next decade, and then rose in the early 1980s. In 1993 the rate was 15.1 percent, the highest since 1983. Between 1993 and 2000 the rate turned downward, falling to 11.3 percent in 2000. Because of recession, slow employment growth, and relatively slow wage growth, the poverty rate rose from 11.7 percent in 2001 to 12.7 percent in 2004. During the second half of the 1990s, poverty rates plunged for African Americans, Hispanics, and Asians, and they have remained historically low. Nevertheless, in 2008 African Americans and Hispanics still had poverty rates that were roughly double the rate for whites.

The recession that began in December 2007 increased poverty rates for all groups with, for instance, the Asian poverty rate rising from 10.2 percent in 2007 to 11.8 percent in

2008. As data became available for the years 2009 to 2011, many economists were surprised that poverty rates appeared to level off or fall despite the widespread and lingering unemployment caused by the so-called Great Recession.

Measurement Issues

The poverty rates and trends in Figures 23.4 and 23.5 should be interpreted cautiously. The official income thresholds for defining poverty are necessarily arbitrary and therefore may inadequately measure the true extent of poverty in the United States.

Some observers say that the high cost of living in major metropolitan areas means that the official poverty thresholds exclude millions of families whose income is slightly above the poverty level but clearly inadequate to meet basic needs for food, housing, and medical care. These observers use city-by-city studies on “minimal income needs” to argue that poverty in the United States is much more widespread than officially measured and reported.

In contrast, some economists point out that using income to measure poverty understates the standard of living of many of the people who are officially poor. When individual, household, or family *consumption* is considered rather than family *income*, some of the poverty in the United States disappears. Some low-income families maintain their consumption by drawing down past savings, borrowing against future income, or selling homes. Moreover, many poor families receive substantial noncash benefits such as food stamps and rent subsidies that boost their living standards. Such “in-kind” benefits are not included in determining a family’s official poverty status.

FIGURE 23.5 Poverty-rate trends, 1959–2014. Although the national poverty rate declined sharply between 1959 and 1969, it stabilized in the 1970s only to increase significantly in the early 1980s. Between 1993 and 2000 it substantially declined, before rising slightly again in the immediate years following the 2001 recession. Although poverty rates for African Americans and Hispanics are much higher than the average, they significantly declined during the 1990s. Poverty rates rose in 2008 in response to the recession that began in December 2007.

The U.S. Income-Maintenance System

LO23.6 Identify the major components of the income-maintenance program in the United States.

Regardless of how poverty is measured, economists agree that considerable poverty exists in the United States. Helping those who have very low income is a widely accepted goal of public policy. A wide array of antipoverty programs, including education and training programs, subsidized employment, minimum-wage laws, and antidiscrimination policies, are designed to increase the earnings of the poor. In addition, a number of income-maintenance programs were devised to reduce poverty; the most important are listed in Table 23.3. These programs involve large expenditures and have numerous beneficiaries.

The U.S. income-maintenance system consists of two kinds of programs: (1) social insurance and (2) public assistance, or “welfare.” Both are known as **entitlement programs** because all eligible persons are legally entitled to receive the benefits set forth in the programs.

Social Insurance Programs

Social insurance programs partially replace earnings that have been lost due to retirement, disability, or temporary unemployment; they also provide health insurance for the

elderly. The main social insurance programs are Social Security, unemployment compensation, and Medicare. Benefits are viewed as earned rights and do not carry the stigma of public charity. These programs are financed primarily out of federal payroll taxes. In these programs the entire population shares the risk of an individual’s losing income because of retirement, unemployment, disability, or illness. Workers (and employers) pay a part of wages into a government fund while they are working. The workers are then entitled to benefits when they retire or when a specified misfortune occurs.

Social Security and Medicare The major social insurance program is known as **Social Security**. It is a federal pension program that replaces part of the earnings lost when workers retire, become disabled, or die. This gigantic program (\$882 billion in 2014) is financed by compulsory payroll taxes levied on both employers and employees. Workers currently may retire at age 65 and receive full retirement benefits or retire early at age 62 with reduced benefits. When a worker dies, benefits accrue to his or her family survivors. Special provisions provide benefits for disabled workers.

Social Security covers over 90 percent of the workforce; some 59 million people receive Social Security benefits, with benefits for retirees averaging about \$1,230 per month. In 2014, those benefits were financed with a combined Social Security and Medicare payroll tax of 15.3 percent, with both

the worker and the employer paying 7.65 percent on their first \$118,500 of earnings. The 7.65 percent tax comprises 6.2 percent for Social Security and 1.45 percent for Medicare. Self-employed workers pay a tax of 15.3 percent.

Medicare is a federal insurance program that provides health insurance benefits to those 65 or older and people who are disabled. It is financed by payroll taxes on employers and employees. This overall 2.9 percent tax is paid on all work income, not just on the first \$118,500. Medicare also makes available supplementary low-cost insurance programs that help pay for doctor visits and prescription drug expenses. In 2014, some 54 million people received Medicare benefits. The benefits paid to recipients totaled \$634 billion.

The number of retirees drawing Social Security and Medicare benefits is rapidly rising relative to the number of workers paying payroll taxes. As a result, Social Security and Medicare face serious long-term funding problems. These fiscal imbalances have spawned calls to reform the programs.

Unemployment Compensation All 50 states sponsor unemployment insurance programs called **unemployment compensation**, a federal–state social insurance program that makes income available to workers who are unemployed.

This insurance is financed by a relatively small payroll tax, paid by employers, which varies by state and by the size of the firm’s payroll. Any insured worker who becomes unemployed can, after a short waiting period, become eligible for benefit payments. The program covers almost all wage and salary workers. The size of payments and the number of weeks they are made available vary considerably from state to state. Generally, benefits approximate 33 percent of a worker’s wages up to a certain maximum payment. In 2014 benefits averaged about \$333 weekly. The number of beneficiaries and the level of total disbursements varies with economic conditions.

Typically, unemployment compensation payments last a maximum of 26 weeks. But during recessions—when unemployment rates soar—Congress extends the benefits for additional weeks.

Public Assistance Programs

Public assistance programs (welfare) provide benefits to people who are unable to earn income because of permanent disabling conditions or who have no or very low income and also have dependent children. These programs are financed out of

Welfare Cliffs

A welfare cliff occurs when an employed welfare recipient's overall income (= wages they earn from work + government benefits)

will fall if they earn more money at work. This happens because many types of welfare benefits are withdrawn abruptly if the recipient's income rises above a particular level.

As an example, a single mother named Linda earning wages of \$30,000 per year in the state of Pennsylvania would qualify for about \$7,000 in housing credits, which would raise her overall income to \$37,000. But the housing credits are withdrawn for anyone earning more than \$30,000 per year. Thus, if Linda went out and earned an extra \$1,000 per year, her overall income would actually fall by \$6,000 (= \$1,000 more earned income minus \$7,000 of lost housing credits).

Welfare cliffs discourage welfare recipients from working more, transitioning into higher-paying jobs, or undertaking the education and training that could lead to higher income levels. One solution would be to have welfare benefits taper off gently as earned income rises. In our example, suppose that Linda's housing credit fell by only \$500 (rather than \$7,000) when she earned that extra \$1,000. In that case, she would come out \$500 ahead and thus have an incentive to work more.

general tax revenues and are regarded as public charity. They include "means tests" that require that individuals and families demonstrate low incomes in order to qualify for aid. The federal government finances about two-thirds of the welfare program expenditures, and the rest is paid for by the states.

Many needy persons who do not qualify for social insurance programs are assisted through the federal government's **Supplemental Security Income (SSI)** program. This is a federal program (financed by general tax revenues) that provides a uniform nationwide minimum income for the aged, blind, and disabled who are unable to work and who do not qualify for Social Security aid. In 2014 the average monthly payment was \$733 for individuals and \$1,100 for couples with both people eligible. More than half the states provide additional income supplements to the aged, blind, and disabled.

Temporary Assistance for Needy Families (TANF) is the basic welfare program for low-income families in the United States. The program is financed through general

federal tax revenues and consists of lump-sum payments of federal money to states to operate their own welfare and work programs. These lump-sum payments are called TANF funds, and in 2014 about 3.5 million people (including children) received TANF assistance. TANF expenditures in 2014 were about \$10 billion.

In 1996 TANF replaced the six-decade-old Aid for Families with Dependent Children (AFDC) program. Unlike that welfare program, TANF established work requirements and placed limits on the length of time a family can receive welfare payments. Specifically, the TANF program:

- Set a lifetime limit of 5 years on receiving TANF benefits and requires able-bodied adults to work after receiving assistance for 2 years.
- Ended food-stamp eligibility for able-bodied persons age 18 to 50 (with no dependent children) who are not working or engaged in job-training programs.
- Tightened the definition of "disabled children" as it applies for eligibility of low-income families for Supplemental Security Income (SSI) assistance.
- Established a 5-year waiting period on public assistance for new legal immigrants who have not become citizens.

In 1996, about 12.6 million people, or about 4.8 percent of the U.S. population, were welfare recipients. By the middle of 2007 those totals had declined to 3.9 million and 1.3 percent of the population. The recession that began in December 2007 pushed the number of welfare recipients up to about 4.4 million by December 2009. These recipients accounted for about 1.4 percent of the population in December 2009.

The welfare program has greatly increased the employment rate (= employment/population) for single mothers with children under age 6—a group particularly prone to welfare dependency. Today, that rate is about 13 percentage points higher than it was in 1996.

The **Supplemental Nutrition Assistance Program (SNAP)** was formerly known as the food-stamp program. SNAP is a federal program (financed through general tax revenues) that permits eligible low-income persons to obtain vouchers that can be used to buy food. It is designed to provide all low-income Americans with a nutritionally adequate diet. Under the program, eligible households receive monthly deposits of spendable electronic money on specialized debit cards known as Electronic Benefit Transfer (EBT) cards. The EBT cards are designed so that the deposits can be spent only on food. The amount deposited onto a family's EBT card varies inversely with the family's earned income.

Medicaid is a federal program (financed by general tax revenues) that provides medical benefits to people covered by the SSI and TANF (basic welfare) programs. It helps finance the medical expenses of individuals participating in those programs.

The **earned-income tax credit (EITC)** is a refundable federal tax credit provided to low-income wage earners to supplement their families' incomes and encourage work. It is available for low-income working families, with or without children. The credit reduces the federal income taxes that such families owe or provides them with cash payments if the credit exceeds their tax liabilities. The purpose of the credit is to offset Social Security taxes paid by low-wage earners and thus keep the federal government from "taxing families into poverty." In essence, EITC is a wage subsidy from the federal government that works out to be as much as \$2 per hour for the lowest-paid workers with families. Under the program many people owe no income tax and receive direct checks from the federal government once a year. According to the Internal Revenue Service, 28 million taxpayers received \$61 billion in payments from the EITC in 2014.

Several other welfare programs are not listed in Table 23.3. Some provide help in the form of noncash transfers. Head Start provides education, nutrition, and social services to economically disadvantaged 3- and 4-year-olds. Housing assistance in the form of rent subsidies and funds for construction is available to low-income families. Pell grants provide assistance to undergraduate students from low-income families. Low-income home energy assistance provides help with home heating bills. Other programs—such as veteran's assistance and black lung benefits—provide cash assistance to those eligible.

QUICK REVIEW 23.2

- ✓ The basic argument for income equality is that it maximizes total utility by equalizing the marginal utility of the last dollar of income received by all people.
- ✓ The basic argument for income inequality is that it is an unavoidable consequence of maintaining the economic incentives for production.
- ✓ By government standards, 46.7 million people in the United States, or 15 percent of the population, lived in poverty in 2014.

Economic Analysis of Discrimination

LO23.7 Discuss labor market discrimination and how it might affect hiring decisions and wages.

Although the majority of Americans who are in the lowest income quintile or in poverty are white, African Americans and Hispanics are in those two categories disproportionately to

their total populations. For that reason, the percentages of all African Americans and Hispanics receiving public assistance from the TANF, SSI, and food stamp programs are also well above the average for the entire population. This fact raises the question of what role, if any, discrimination plays in reducing wages for some and increasing wages for others.

Discrimination is the practice of according people inferior treatment (for example, in hiring, occupational access, education and training, promotion, wage rate, or working conditions) on the basis of some factor such as race, gender, or ethnicity. People who practice discrimination are said to exhibit a prejudice or a bias against the groups they discriminate against.

Prejudice reflects complex, multifaceted, and deeply ingrained beliefs and attitudes. Thus, economics can contribute some insights into discrimination but no detailed explanations. With this caution in mind, let's look more deeply into the economics of discrimination.

Taste-for-Discrimination Model

The **taste-for-discrimination model** examines prejudice by using the emotion-free language of demand theory. It views discrimination as resulting from a preference or taste for which the discriminator is willing to pay. The model assumes that, for whatever reason, prejudiced people experience a subjective or psychic cost—a disutility—whenever they must interact with those they are biased against. Consequently, they are willing to pay a certain "price" to avoid interactions with the nonpreferred group. The size of this price depends directly on the degree of prejudice.

The taste-for-discrimination model is general, since it can be applied to race, gender, age, and religion. But our discussion focuses on employer discrimination, in which employers discriminate against nonpreferred workers. For concreteness, we will look at a white employer discriminating against African-American workers.

Discrimination Coefficient A prejudiced white employer behaves as if employing African-American workers would add a cost. The amount of this cost—this disutility—is reflected in a **discrimination coefficient**, d , measured in monetary units. Because the employer is not prejudiced against whites, the cost of employing a white worker is the white wage rate, W_w . However, the employer's perceived "cost" of employing an African-American worker is the African-American worker's wage rate, W_{aa} , plus the cost d involved in the employer's prejudice, or $W_{aa} + d$.

The prejudiced white employer will have no preference between African-American and white workers when the total cost per worker is the same, that is, when $W_w = W_{aa} + d$. Suppose the market wage rate for whites is \$10 and the monetary value of the disutility the employer attaches to hiring African

Americans is \$2 (that is, $d = \$2$). This employer will be indifferent between hiring African Americans and whites only when the African-American wage rate is \$8, since at this wage the perceived cost of hiring either a white or an African-American worker is \$10:

$$\begin{aligned} \$10 \text{ white wage} &= \$8 \text{ African-American wage} + \\ &\quad \$2 \text{ discrimination coefficient} \end{aligned}$$

It follows that our prejudiced white employer will hire African Americans only if their wage rate is sufficiently below that of whites. By “sufficiently” we mean at least the amount of the discrimination coefficient.

The greater a white employer’s taste for discrimination as reflected in the value of d , the larger the difference between white wages and the lower wages at which African Americans will be hired. A “color-blind” employer whose d is \$0 will hire equally productive African Americans and whites impartially if their wages are the same. A blatantly prejudiced white employer whose d is infinity would refuse to hire African Americans even if the African-American wage were zero.

Most prejudiced white employers will not refuse to hire African Americans under all conditions. They will, in fact, *prefer* to hire African Americans if the actual white-black wage difference in the market exceeds the value of d . In our example, if whites can be hired at \$10 and equally productive African Americans at only \$7.50, the biased white employer will hire African Americans. That employer is willing to pay a wage difference of up to \$2 per hour for whites to satisfy his or her bias, but no more. At the \$2.50 actual difference, the employer will hire African Americans.

Conversely, if whites can be hired at \$10 and African Americans at \$8.50, whites will be hired. Again, the biased employer is willing to pay a wage difference of up to \$2 for whites; a \$1.50 actual difference means that hiring whites is a “bargain” for this employer.

Prejudice and the Market African-American–White Wage Ratio For a particular supply of African-American workers, the actual African-American–white wage ratio—the ratio determined in the labor market—will depend on the collective prejudice of white employers. To see why, consider Figure 23.6, which shows a labor market for African-American workers. Initially, suppose the relevant labor demand curve is D_1 , so the equilibrium African-American wage is \$8 and the equilibrium level of African-American employment is 16 million. If we assume that the white wage (not shown) is \$10, then the initial African-American–white wage ratio is 0.8 ($= \$8/\10).

Now assume that prejudice against African-American workers increases—that is, the collective d of white employers rises. An increase in d means an increase in the perceived cost of African-American labor at each African-American wage rate, and that reduces the demand for African-American

FIGURE 23.6 The African-American wage and employment level in the taste-for-discrimination model. An increase in prejudice by white employers as reflected in higher discrimination coefficients would decrease the demand for African-American workers, here from D_1 to D_2 , and reduce the African-American wage rate and level of African-American employment. Not shown, this drop in the African-American wage rate would lower the African-American–white wage ratio. In contrast, if prejudice were reduced such that discrimination coefficients of employers declined, the demand for African-American labor would increase, as from D_1 to D_3 , boosting the African-American wage rate and level of employment. The higher African-American wage rate would increase the African-American–white wage ratio.

labor, say, from D_1 to D_2 . The African-American wage rate falls from \$8 to \$6 in the market, and the level of African-American employment declines from 16 million to 12 million. The increase in white employer prejudice reduces the African-American wage rate and thus the actual African-American–white wage ratio. If the white wage rate remains at \$10, the new African-American–white ratio is 0.6 ($= \$6/\10).

Conversely, suppose social attitudes change such that white employers become less biased and their discrimination coefficient as a group declines. This decreases the perceived cost of African-American labor at each African-American wage rate, so the demand for African-American labor increases, as from D_1 to D_3 . In this case, the African-American wage rate rises to \$9, and employment of African-American workers increases to 18 million. The decrease in white employer prejudice increases the African-American wage rate and thus the actual African-American–white wage ratio. If the white wage remains at \$10, the new African-American–white wage ratio is 0.9 ($= \$9/\10).

Competition and Discrimination The taste-for-discrimination model suggests that competition will reduce discrimination in the very long run, as follows: The actual African-American–white wage difference for equally productive

workers—say, \$2—allows nondiscriminators to hire African Americans for less than whites. Firms that hire African-American workers will therefore have lower actual wage costs per unit of output and lower average total costs than will the firms that discriminate. These lower costs will allow nondiscriminators to underprice discriminating competitors, eventually driving them out of the market.

But critics of this implication of the taste-for-discrimination model say that it overlooks entry barriers to new firms and point out that progress in eliminating racial discrimination has been slow. Discrimination based on race has persisted in the United States and other market economies decade after decade. To explain why, economists have proposed alternative models.

Statistical Discrimination

A second theory of discrimination centers on the concept of **statistical discrimination**, in which people are judged on the basis of the average characteristics of the group to which they belong, rather than on their own personal characteristics or productivity. For example, insurance rates for teenage males are higher than those for teenage females. The difference is based on factual evidence indicating that, on average, young males are more likely than young females to be in accidents. But many young men are actually less accident-prone than the average young woman, and those men are discriminated against by having to pay higher insurance rates. The uniqueness of the theory of statistical discrimination is its suggestion that discriminatory outcomes are possible even where there is no prejudice.

Labor Market Example How does statistical discrimination show itself in labor markets? Employers with job openings want to hire the most productive workers available. They have their personnel department collect information concerning each job applicant, including age, education, and prior work experience. They may supplement that information with preemployment tests, which they feel are helpful indicators of potential job performance. But collecting detailed information about job applicants is very expensive, and predicting job performance on the basis of limited data is difficult. Consequently, some employers looking for inexpensive information may consider the *average* characteristics of women and minorities in determining whom to hire. They are in fact practicing statistical discrimination when they do so. They are using gender, race, or ethnic background as a crude indicator of production-related attributes.

Example: Suppose an employer who plans to invest heavily in training a worker knows that on average women are less likely to be career-oriented than men, more likely to quit work in order to care for young children, and more likely to refuse geographic transfers. Thus, on average, the return on

the employer's investment in training is likely to be less when choosing a woman than when choosing a man. All else equal, when choosing between two job applicants, one a woman and the other a man, this employer is likely to hire the man.

Note what is happening here. Average characteristics for a *group* are being applied to *individual* members of that group. The employer is falsely assuming that *each and every* woman worker has the same employment tendencies as the *average* woman. Such stereotyping means that numerous women who are career-oriented, who do not plan on quitting work in order to care for young children, and who are flexible as to geographic transfers will be discriminated against.

Profitable, Undesirable, but Not Malicious The firm that practices statistical discrimination is not being malicious in its hiring behavior (although it may be violating antidiscrimination laws). The decisions it makes will be rational and profitable because *on average* its hiring decisions are likely to be correct. Nevertheless, many people suffer because of statistical discrimination, since it blocks the economic betterment of capable people. And since it is profitable, statistical discrimination tends to persist.

Occupational Segregation: The Crowding Model

The practice of **occupational segregation**—the crowding of women, African Americans, and certain ethnic groups into less desirable, lower-paying occupations—is still apparent in the U.S. economy. Statistics indicate that women are disproportionately concentrated in a limited number of occupations such as teaching, nursing, and secretarial and clerical jobs. African Americans and Hispanics are crowded into low-paying jobs such as those of laundry workers, cleaners and household aides, hospital orderlies, agricultural workers, and other manual laborers.

Let's look at a model of occupational segregation, using women and men as an example.

The Model The character and income consequences of occupational discrimination are revealed through a labor supply and demand model. We make the following assumptions:

- The labor force is equally divided between men and women workers. Let's say there are 6 million male and 6 million female workers.
- The economy comprises three occupations, X, Y, and Z, with identical labor demand curves, as shown in Figure 23.7.
- Men and women have the same labor-force characteristics; each of the three occupations could be filled equally well by men or by women.

FIGURE 23.7 The economics of occupational segregation. (a) Because 1 million women are excluded from occupation X, the wage rate for men in that occupation is M rather than B . (b) Because another 1 million women are excluded from occupation Y, the wage for men in occupation Y is also M rather than B . (c) Because the 2 million women excluded from occupations X and Y are crowded into occupation Z, the wage rate for women there is W rather than B . The elimination of discrimination will create flows of 1 million women to occupation X and 1 million women to occupation Y. The wage rate will equalize at B in all three occupations and the nation's output will rise by the sum of the two blue areas minus the single green area.

Effects of Crowding Suppose that, as a consequence of discrimination, the 6 million women are excluded from occupations X and Y and crowded into occupation Z, where they earn wage W . The men distribute themselves equally among occupations X and Y, meaning that 3 million male workers are in each occupation and have a common wage of M . (If we assume that there are no barriers to mobility between X and Y, any initially different distribution of males between X and Y would result in a wage differential between the two occupations. That would prompt labor shifts from the low- to the high-wage occupation until an equal distribution occurred.)

Because women are crowded into occupation Z, labor supply (not shown) is larger and their wage rate W is much lower than M . Because of the discrimination, this is an equilibrium situation that will persist as long as the crowding occurs. The occupational barrier means women cannot move into occupations X and Y in pursuit of a higher wage.

The result is a loss of output for society. To see why, recall again that labor demand reflects labor's marginal revenue product, which is labor's contribution to domestic output. Thus, the blue areas for occupations X and Y in Figure 23.7 show the decrease in domestic output—the market value of the marginal output—caused by subtracting 1 million women from each of these occupations. Similarly, the green area for occupation Z shows the increase in domestic output caused by moving 2 million women into occupation Z. Although society would gain the added output represented by the green area in occupation Z, it would lose the output represented by the sum of the two blue areas in occupations X and Y. That output loss exceeds the output gain, producing a net output loss for society.

Eliminating Occupational Segregation Now assume that through legislation or sweeping changes in social attitudes,

discrimination disappears. Women, attracted by higher wage rates, shift from occupation Z to X and Y; 1 million women move into X and another 1 million move into Y. Now there are 4 million workers in Z, and occupational segregation is eliminated. At that point there are 4 million workers in each occupation, and wage rates in all three occupations are equal, here at B . That wage equality eliminates the incentive for further reallocations of labor.

The new, nondiscriminatory equilibrium clearly benefits women, who now receive higher wages; it hurts men, who now receive lower wages. But women were initially harmed and men benefited through discrimination; removing discrimination corrects that situation.

Society also gains. The elimination of occupational segregation reverses the net output loss just discussed. Adding 1 million women to each of occupations X and Y in Figure 23.7 increases domestic output by the sum of the two blue areas. The decrease in domestic output caused by losing 2 million women from occupation Z is shown by the green area. The sum of the two increases in domestic output in X and Y exceeds the decrease in domestic output in Z. With the end of the discrimination, 2 million women workers have moved from occupation Z, where their contribution to domestic output (their MRP) is low, to higher-paying occupations X and Y, where their contribution to domestic output is high. Thus society gains a more efficient allocation of resources from the removal of occupational discrimination.

Example: The easing of occupational barriers has led to a surge of women gaining advanced degrees in some high-paying professions. In recent years, for instance, the percentage of law degrees and medical degrees awarded to women has exceeded 50 percent, compared with less than 10 percent in 1970.

U.S. Family Wealth and Its Distribution

Between 1995 and 2010, Family Wealth Rose Rapidly for Both the Typical Family as Well as Very Well-Off Families. But Then the Collapse of the Housing Bubble and the Recession of 2007–2009 Greatly Reduced the Typical Family’s Level of Wealth.

The latest findings on U.S. family wealth (= net worth = assets *minus* liabilities) were reported in 2014. The data were obtained from the Survey of Consumer Finances and *The State of Working America*. The information includes data on median family wealth, average family wealth, and the distribution of wealth in the United States. *Median family wealth* is the wealth received by the family at the midpoint of the wealth distribution; *average family wealth* is simply total wealth divided by the number of families.

As shown in Table 1, median and average family wealth, adjusted for inflation, both grew rapidly between 1995 and 2007. But then the 2007–2009 recession caused both to drop precipitously. Median wealth, in particular, fell so far that its 2010 value of \$77,300 was nearly 8 percent lower than the \$84,000 value observed 15 years earlier, in 1995. Even worse, the decline continued over the next few years, with the 2013 value falling to \$76,000, or about 10 percent less than the 1995 value.

Most of the decline was due to the 30 percent fall in average housing prices that took place during and after the recession. Millions of people who had taken out loans to buy houses found themselves “underwater” on their home mortgages because the market values of their homes had fallen below what they owed on their loans. That meant that they had *negative* wealth in terms of their housing purchases. As a result, overall wealth levels dropped sharply.

Table 2 looks at the distribution of family wealth for various percentile groups and reveals that the distribution of wealth is highly unequal. In 2010 the wealthiest 10 percent of families owned almost 77 percent of the total wealth and the top 1 percent owned about 35 percent. By contrast, the bottom 90 percent held only about 23 percent of the total wealth. Moreover, the general trend is toward greater inequality. The

lowest 90 percent of families saw their share fall from about 32 percent of total U.S. wealth in 1995 to only about 23 percent in 2010.

Tables 1 and 2 raise many interesting questions: Will the inequality of wealth continue to grow in the future? If so, what are the implications for the future character of American society? Should government do more, or less, in the future to try to redistribute wealth? Would new government policies to redistribute wealth endanger or slow the creation of wealth and the growth of income for average Americans? As of 2016, the federal estate (inheritance) tax had a zero percent rate up to \$5.43 million and then a 40 percent rate on anything above \$5.43 million. There is a vigorous debate about whether this represents too much or too little in the way of estate taxation.

Cost to Society as Well as to Individuals

It is obvious from all three models of discrimination that discrimination by characteristics such as race, ethnicity, gender, or age imposes costs on those who are discriminated against. They have lower wages, less access to jobs, or both. Preferred workers in turn benefit from discrimination through less job competition, greater job access, and higher wages. But discrimination does more than simply transfer earnings from some people to others, thus contributing to income inequality and increasing poverty. Where it exists, discrimination also diminishes the economy's total output and income. In that regard, discrimination acts much like any other artificial barrier to free competition. By arbitrarily blocking qualified individuals from high-productivity (and thus high-wage) jobs, discrimination keeps those discriminated against from providing their maximum contribution to society's total output and total income. In terms of production possibilities analysis, discrimination locates society inside the production possibilities curve that would be available to it if there were no discrimination.

Discrimination redistributes a diminished amount of total income.

QUICK REVIEW 23.3

- ✓ Discrimination occurs when workers who have the same abilities, education, training, and experience as other workers receive inferior treatment with respect to hiring, occupational access, promotion, or wages.
- ✓ The taste-for-discrimination model sees discrimination as representing a preference or "taste" for which the discriminator is willing to pay.
- ✓ The theory of statistical discrimination says that employers often wrongly judge individuals on the basis of average group characteristics rather than on personal characteristics, thus harming those discriminated against.
- ✓ The crowding model of discrimination suggests that when women and minorities are systematically excluded from high-paying occupations and crowded into low-paying ones, their wages and society's domestic output are reduced.

SUMMARY

L023.1 Explain how income inequality in the United States is measured and described.

The distribution of income in the United States reflects considerable inequality. The richest 20 percent of households receive 51.2 percent of total income, while the poorest 20 percent receive 3.1 percent.

The Lorenz curve shows the percentage of total income received by each percentage of households. The extent of the gap between the Lorenz curve and a line of total equality illustrates the degree of income inequality.

The Gini ratio measures the overall dispersion of the income distribution and is found by dividing the area between the diagonal and the Lorenz curve by the entire area below the diagonal. The Gini ratio ranges from zero to 1, with higher ratios signifying greater degrees of income inequality.

L023.2 Discuss the extent and sources of income inequality.

Recognizing that the positions of individual families in the distribution of income change over time and incorporating the effects of noncash transfers and taxes would reveal less income inequality than do standard census data. Government transfers (cash and noncash) greatly lessen the degree of income inequality; taxes also reduce inequality, but not nearly as much as transfers.

Causes of income inequality include differences in abilities, in education and training, and in job tastes, along with discrimination, inequality in the distribution of wealth, and an unequal distribution of market power.

L023.3 Demonstrate how income inequality has changed since 1975.

Census data show that income inequality has increased since 1975. The major cause of the recent increases in income inequality is a rising demand for highly skilled workers, which has boosted their earnings significantly.

L023.4 Debate the economic arguments for and against income inequality.

The basic argument for income equality is that it maximizes consumer satisfaction (total utility) from a particular level of total income. The main argument for income inequality is that it provides the incentives to work, invest, and assume risk and is necessary for the production of output, which, in turn, creates income that is then available for distribution.

L023.5 Relate how poverty is measured and its incidence by age, gender, ethnicity, and other characteristics.

Current statistics reveal that 15 percent of the U.S. population lives in poverty. Poverty rates are particularly high for female-headed families, young children, African Americans, and Hispanics.

L023.6 Identify the major components of the income-maintenance program in the United States.

The present income-maintenance program in the United States consists of social insurance programs (Social Security, Medicare, and

unemployment compensation) and public assistance programs (SSI, TANF, food stamps, Medicaid, and the earned-income tax credit).

L023.7 Discuss labor market discrimination and how it might affect hiring decisions and wages.

Discrimination relating to the labor market occurs when women or minorities having the same abilities, education, training, and experience as men or white workers are given inferior treatment with respect to hiring, occupational choice, education and training, promotion, and wage rates. Discrimination redistributes national income and, by creating inefficiencies, diminishes its size.

In the taste-for-discrimination model, some white employers have a preference for discrimination, measured by a discrimination coefficient d . Prejudiced white employers will hire African-American workers only if their wages are at least d dollars below

those of whites. The model indicates that declines in the discrimination coefficients of white employers will increase the demand for African-American workers, raising the African-American wage rate and the ratio of African-American wages to white wages. It also suggests that competition may eliminate discrimination in the long run.

Statistical discrimination occurs when employers base employment decisions about *individuals* on the average characteristics of *groups* of workers. That can lead to discrimination against individuals even in the absence of prejudice.

The crowding model of occupational segregation indicates how white males gain higher earnings at the expense of women and certain minorities who are confined to a limited number of occupations. The model shows that discrimination also causes a net loss of domestic output.

DISCUSSION QUESTIONS

1. Use quintiles to briefly summarize the degree of income inequality in the United States. How and to what extent does government reduce income inequality? **L023.1**
2. Assume that Al, Beth, Carol, David, and Ed receive incomes of \$500, \$250, \$125, \$75, and \$50, respectively. Construct and interpret a Lorenz curve for this five-person economy. What percentage of total income is received by the richest quintile and by the poorest quintile? **L023.1**
3. How does the Gini ratio relate to the Lorenz curve? Why can't the Gini ratio exceed 1? What is implied about the direction of income inequality if the Gini ratio declines from 0.42 to 0.35? How would one show that change of inequality in the Lorenz diagram? **L023.1**
4. Why is the lifetime distribution of income more equal than the distribution in any specific year? **L023.1**
5. Briefly discuss the major causes of income inequality. With respect to income inequality, is there any difference between inheriting property and inheriting a high IQ? Explain. **L023.2**
6. What factors have contributed to increased income inequality since 1975? **L023.3**
7. Should a nation's income be distributed to its members according to their contributions to the production of that total income or according to the members' needs? Should society attempt to equalize income or economic opportunities? Are the issues of equity and equality in the distribution of income synonymous? To what degree, if any, is income inequality equitable? **L023.4**
8. Do you agree or disagree? Explain your reasoning. "There need be no trade-off between equality and efficiency. An 'efficient' economy that yields an income distribution that many regard as unfair may cause those with meager incomes to become discouraged and stop trying. So efficiency may be undermined. A fairer distribution of rewards may generate a higher average productive effort on the part of the population, thereby enhancing efficiency. If people think they are playing a fair economic game and this belief causes them to try harder, an economy with an equitable income distribution may be efficient as well."⁷ **L023.4**

⁷Paraphrased from Andrew Schotter, *Free Market Economics* (New York: St. Martin's Press, 1985), pp. 30–31.

9. Comment on or explain: **L023.4**
- Endowing everyone with equal income will make for very unequal enjoyment and satisfaction.
 - Equality is a “superior good”; the richer we become, the more of it we can afford.
 - The mob goes in search of bread, and the means it employs is generally to wreck the bakeries.
 - Some freedoms may be more important in the long run than freedom from want on the part of every individual.
 - Capitalism and democracy are really a most improbable mixture. Maybe that is why they need each other—to put some rationality into equality and some humanity into efficiency.
 - The incentives created by the attempt to bring about a more equal distribution of income are in conflict with the incentives needed to generate increased income.
10. How do government statisticians determine the poverty rate? How could the poverty rate fall while the number of people in poverty rises? Which group in each of the following pairs has the higher poverty rate: (a) children or people age 65 or over? (b) African Americans or foreign-born noncitizens? (c) Asians or Hispanics? **L023.5**
11. What are the essential differences between social insurance and public assistance programs? Why is Medicare a social insurance program, whereas Medicaid is a public assistance program? Why is the earned-income tax credit considered to be a public assistance program? **L023.6**
12. The labor demand and supply data in the following table relate to a single occupation. Use them to answer the questions that follow. Base your answers on the taste-for-discrimination model. **L023.7**

Quantity of Hispanic Labor Demanded, Thousands	Hispanic Wage Rate	Quantity of Hispanic Labor Supplied, Thousands
24	\$16	52
30	14	44
35	12	35
42	10	28
48	8	20

- Plot the labor demand and supply curves for Hispanic workers in this occupation.
 - What are the equilibrium Hispanic wage rate and quantity of Hispanic employment?
 - Suppose the white wage rate in this occupation is \$16. What is the Hispanic-to-white wage ratio?
 - Suppose a particular employer has a discrimination coefficient d of \$5 per hour. Will that employer hire Hispanic or white workers at the Hispanic-white wage ratio indicated in part *c*? Explain.
 - Suppose employers as a group become less prejudiced against Hispanics and demand 14 more units of Hispanic labor at each Hispanic wage rate in the table. What are the new equilibrium Hispanic wage rate and level of Hispanic employment? Does the Hispanic-white wage ratio rise or fall? Explain.
 - Suppose Hispanics as a group increase their labor services in that occupation, collectively offering 14 more units of labor at each Hispanic wage rate. Disregarding the changes indicated in part *e*, what are the new equilibrium Hispanic wage rate and level of Hispanic employment? Does the Hispanic-white wage ratio rise, or does it fall?
13. Males under the age of 25 must pay far higher auto insurance premiums than females in this age group. How does this fact relate to statistical discrimination? Statistical discrimination implies that discrimination can persist indefinitely, while the taste-for-discrimination model suggests that competition might reduce discrimination in the long run. Explain the difference. **L023.7**
14. Use a demand-and-supply model to explain the impact of occupational segregation or “crowding” on the relative wage rates and earnings of men and women. Who gains and who loses from the elimination of occupational segregation? Is there a net gain or a net loss to society? Explain. **L023.7**
15. **LAST WORD** Go to Table 1 in the Last Word and compute the ratio of average wealth to median wealth for each of the 7 years. What trend do you find? What is your explanation for the trend? The federal estate tax redistributes wealth in two ways: by encouraging charitable giving, which reduces the taxable estate, and by heavily taxing extraordinarily large estates and using the proceeds to fund government programs. Do you favor repealing the estate tax? Explain.

REVIEW QUESTIONS

- Suppose that the United States has a Gini ratio of 0.41 while Sweden has a Gini ratio of 0.31. Which country has a more equal distribution of income? **L023.1**
 - The United States.
 - Sweden.
 - They are actually equal.
- Some part of income inequality is likely to be the result of discrimination. But other factors responsible for inequality include (select as many as apply): **L023.2**
 - Differences in abilities and talents.
 - Differences in education and training.
 - Different preferences for work versus leisure.
 - Different preferences for low-paying but safe jobs relative to high-paying but dangerous jobs.
- Suppose that a society contains only two members, a lawyer named Monique and a handyman named James. Five years ago, Monique made \$100,000 while James made \$50,000. This year, Monique will make \$300,000 while James will make \$100,000. Which of the following statements about this society’s income distribution are true? **L023.2**

Select **one or more** answers from the choices shown.

- a. In absolute dollar amounts, the entire distribution of income has been moving upward.
 - b. In absolute dollar amounts, the entire distribution of income has been stagnant.
 - c. The relative distribution of income has become more equal.
 - d. The relative distribution of income has become less equal.
 - e. The relative distribution of income has remained constant.
 - f. The rich are getting richer while the poor are getting poorer.
 - g. The rich are getting richer faster than the poor are getting richer.
4. Suppose that the last dollar that Victoria receives as income brings her a marginal utility of 10 utils while the last dollar that Fredrick receives as income brings him a marginal utility of 15 utils. If our goal is to maximize the combined total utility of Victoria and Fredrick, we should: **L023.4**
- a. Redistribute income from Victoria to Fredrick.
 - b. Redistribute income from Fredrick to Victoria.
 - c. Not engage in any redistribution because the current situation already maximizes total utility.
 - d. None of the above.
5. If women are crowded into elementary education and away from fire fighting, wages in fire fighting will tend to be _____ than if women weren't crowded into elementary education. **L023.7**
- a. Higher.
 - b. Lower.
6. In the taste-for-discrimination model, an increase in employer prejudice against African-American workers would cause the discrimination coefficient to _____ and the demand curve for African-American labor to shift _____.
- L023.7**
- a. Decrease; right.
 - b. Decrease; left.
 - c. Increase; right.
 - d. Increase; left.

PROBLEMS

1. In 2015, *Forbes* magazine listed Bill Gates, the founder of Microsoft, as the richest person in the United States. His personal wealth was estimated to be \$76 billion. Given that there were about 322 million people living in the United States that year, how much could each person have received if Gates's wealth had been divided equally among the population of the United States? (Hint: A billion is a 1 followed by 9 zeros while a million is a 1 followed by six zeros.) **L023.1**
2. Imagine an economy with only two people. Larry earns \$20,000 per year, while Roger earns \$80,000 per year. As shown in the following figure, the Lorenz curve for this two-person economy consists of two line segments. The first runs from the origin to point *a*, while the second runs from point *a* to point *b*. **L023.1**

- a. Calculate the Gini ratio for this two-person economy using the geometric formulas for the area of a triangle ($= \frac{1}{2} \times \text{base} \times \text{height}$) and the area of a rectangle ($= \text{base} \times \text{height}$). (Hint: The area under the line segment from point *a* to point *b* can be thought of as the sum of the area of a particular triangle and the area of a particular rectangle.)
 - b. What would the Gini ratio be if the government taxed \$20,000 away from Roger and gave it to Larry? (Hint: The figure will change.)
 - c. Start again with Larry earning \$20,000 per year and Roger earning \$80,000 per year. What would the Gini ratio be if both their incomes doubled? How much has the Gini ratio changed from before the doubling in incomes to after the doubling in incomes?
3. In 2015, many unskilled workers in the United States earned the federal minimum wage of \$7.25 per hour. By contrast, average earnings in 2015 were about \$23 per hour, and certain highly skilled professionals, such as doctors and lawyers, earned \$100 or more per hour. **L023.6**
- a. If we assume that wage differences are caused solely by differences in productivity, how many times more productive was the average worker than a worker being paid the federal minimum wage? How many times more productive was a \$100-per-hour lawyer compared to a worker earning minimum wage?
 - b. Assume that there are 20 minimum-wage workers in the economy for each \$100-per-hour lawyer. Also assume that both lawyers and minimum-wage workers work the same number of hours per week. If everyone works 40 hours per week, how much does a \$100-per-hour lawyer earn a week? How much does a minimum-wage worker earn a week?
 - c. Suppose that the government pairs each \$100-per-hour lawyer with 20 nearby minimum-wage workers. If the government taxes 25 percent of each lawyer's income each

week and distributes it equally among the 20 minimum-wage workers with whom each lawyer is paired, how much will each of those minimum-wage workers receive each week? If we divide by the number of hours worked each week, how much does each minimum-wage worker's weekly transfer amount to on an hourly basis?

- d. What if instead the government taxed each lawyer 100 percent before dividing the money equally among the 20 minimum-wage workers with whom each lawyer is paired—how much per week will each minimum-wage worker receive? And how much is that on an hourly basis?
4. The desire to maximize profits can work against racial and other types of discrimination. To see this, consider two equally productive accountants named Ted and Jared. Ted is black, and Jared is white. Both can complete 10 audits per month. **LO23.7**
- a. Suppose that for any accounting firm that hires either Ted or Jared, all the other costs of performing an audit (besides paying either Ted or Jared) come to \$1,000 per audit. If the

going rate that must be paid to hire an accountant is \$7,000 per month, how much will it cost an accounting firm to produce one audit if it hires either Ted or Jared to do the work?

- b. If the market price that accounting firms charge their clients for an audit is \$1,800, what would the accounting profit per audit be for a firm that hired either Ted or Jared? What is the profit rate as a percentage?
- c. Suppose that firm *A* dislikes hiring black accountants, while firm *B* is happy to hire them. So Ted ends up working at firm *B* rather than firm *A*. If Ted works 11 months per year, how many audits will he complete for firm *B* each year? How much in accounting profits will firm *B* earn each year from those audits?
- d. Because firm *A* passed on hiring Ted because he was black, firm *A* is forgoing the profits it could have earned if it had hired Ted. If the firm is willing to forgo up to \$5,000 per year in profit to avoid hiring blacks, by how many dollars will firm *A* regret its decision not to hire Ted?

- LO24.1** Convey important facts about rising health care costs in the United States.
- LO24.2** Relate the economic implications of rising health care costs.
- LO24.3** Discuss the problem of limited access to health care for those without insurance.
- LO24.4** List the demand and supply factors explaining rising health care costs.
- LO24.5** Describe the cost-containment strategies that rely on altering the financial incentives facing either patients or health service providers.
- LO24.6** Summarize the goals of the Patient Protection and Affordable Care Act and the major changes that it institutes.

On March 23, 2010, President Barack Obama signed into law the **Patient Protection and Affordable Care Act (PPACA)**, a wide-ranging law that proponents claimed would lower health care costs while increasing access to quality health care for millions of poorer Americans.

At over 2,400 pages, the legislation was designed to address a wide set of concerns relating to the provision, delivery, and cost of health care. These included the high and rapidly rising cost of health insurance for those who did have health insurance, the fact that tens of millions of Americans at any given moment were without health insurance, and the inability of many people with preexisting conditions to obtain health insurance.

The controversial law gave the federal government sweeping new powers to promote universal insurance coverage and to regulate the details of insurance policies. Because health care spending was 17.9 percent of GDP in 2010, the law effectively put the federal government in control of nearly one-fifth of the U.S. economy. This chapter applies microeconomic analysis to help explain the origin of the problems that the law was designed to address as well as the heated debate over whether the policies prescribed by the law are likely to achieve their goals.

The Health Care Industry

LO24.1 Convey important facts about rising health care costs in the United States.

Because the boundaries of the health care industry are not precise, defining the industry is difficult. In general, it includes services provided in hospitals, nursing homes,

laboratories, and physicians' and dentists' offices. It also includes prescription and nonprescription drugs, artificial limbs, and eyeglasses. Note, however, that many goods and services that may affect health are not included, for example, low-fat foods, vitamins, and health club services.

Health care is one of the largest U.S. industries, employing about 19 million people, including about 708,300 practicing physicians, or 245 doctors per 100,000 of population. There are about 5,600 hospitals containing 902,200 beds. Americans make more than 1 billion visits to office-based physicians each year.

The U.S. Emphasis on Private Health Insurance

Many of the provisions of the Patient Protection and Affordable Care Act are focused on health insurance. This is because a high proportion of health care spending in the United States is provided through private health insurance policies paid for by employers. By contrast, many countries such as Canada have systems of **national health insurance** in which the government uses tax revenues to provide a basic package of health care to every resident at either no charge or at low cost-sharing levels. In such countries only a relatively few people bother to buy private health insurance—and then only to cover services that are not paid for by the national health insurance system.

The uniquely American emphasis on private health insurance paid for by employers is a relatively recent phenomenon. It began during the Second World War in response to price and wage controls that the federal government imposed to prevent inflation. The wage controls were problematic for the private companies charged with building the tanks, planes, and boats needed to win the war. These firms needed to expand output rapidly and knew that doing so would be possible only if they could attract workers away from other industries. Several manufacturers stumbled on the strategy of offering free health insurance as a way of attracting workers. Unable to raise wages, the companies recruited the workers they needed by offering health insurance as a fringe benefit paid for by the employer.

After the war, price and wage controls were lifted. Nevertheless, more and more companies began to offer “free” health insurance to their employees. They did so because of a provision in the federal tax law that makes it cheaper for companies to purchase insurance for their employees than it would be for employees to purchase insurance on their own behalf. By 2007, this incentive structure led to a situation in which nearly 88 percent of people with private health insurance received it as a benefit provided by their employer rather than by purchasing it themselves directly from an insurance company.

The prominence of employer-provided health insurance in the United States has had several important consequences. Perhaps the most important is that health care paid for via

insurance can create perverse incentives for overuse that, in turn, lead to higher prices.

Another consequence of employer-provided health care is that health care reform efforts have focused on regulating the health insurance system with which most people are familiar rather than attempting alternatives that most people have never experienced. Later, we will explore how this tendency to regulate—rather than replace—the current insurance system has affected recent reform efforts including the Patient Protection and Affordable Care Act.

Twin Problems: Costs and Access

In recent decades, the U.S. health care system has suffered from two highly publicized problems:

- The cost of health care has risen rapidly in response to higher prices and an increase in the quantity of services provided. (Spending on health care involves both “prices” and “quantities” and is often loosely referred to as “health care costs.”) The price of medical care has traditionally increased faster than the overall price level in nearly all periods. The December-to-December index of medical care prices rose by 3.3 percent in 2010, 3.5 percent in 2011, 3.2 percent in 2012, 2.0 percent in 2013, and 3.0 percent in 2014, for a five-year average of 3.0 percent. At the same time, the overall price index for all consumer goods increased by an annual average of 2.0 percent for those five years. However, health care spending (price \times quantity) grew by 3.9 percent in 2010, 3.9 percent in 2011, 3.8 percent in 2012, 2.9 percent in 2013, and 5.3 percent in 2014. It is projected to grow at an annual rate of 5.8 percent over the next 10 years, far faster than inflation.
- Some 30 million Americans in 2015 did not have health insurance coverage and, as a result, had significantly reduced access to quality health care.

Efforts to reform health care have focused on controlling costs and making it accessible to everyone. Those two goals are related, since high and rising prices make health care services unaffordable to a significant portion of the U.S. population. In fact, a dual system of health care may be evolving in the United States. Those with insurance or other financial means receive world-class medical treatment, but many people, because of their inability to pay, often fail to seek out even the most basic treatment. When they do seek treatment, they may receive poorer care than those who have insurance. Free county hospitals and private charity hospitals do provide services to those without insurance, but the quality of care can be considerably lower than that available to people who have insurance.

High and Rising Health Care Costs

We need to examine several aspects of health care costs, or, alternatively, health care spending.

FIGURE 24.1 Health care expenditures and finance. Total U.S. health care expenditures are extremely large (\$3.0 trillion in 2014). (a) Most health care expenditures are for hospitals and the services of physicians and other skilled professionals. (b) Public and private insurance pay for four-fifths of health care.

Health Care Spending Health care spending in the United States is high and rising in both absolute terms and as a percentage of domestic output.

Total Spending on Health Care Figure 24.1a gives an overview of the major types of U.S. health care spending (\$3.0 trillion in 2014). It shows that 32 cents of each health care dollar goes to hospitals, while 20 cents goes to physicians, and 18 cents is spent on dental, vision, and other miscellaneous health care services.

Figure 24.1b shows the sources of funds for health care spending. It reveals that four-fifths of health care spending is financed by insurance. Public insurance (Medicaid, Medicare, and insurance for veterans, current military personnel, and government employees) is the source of 44 cents of each dollar spent. Private insurance accounts for 35 cents. So public and private insurance combined provide 79 cents of each dollar spent. The remaining 21 cents comes directly out of the health care consumer's pocket. It is paid mainly as insurance **deductibles** (that is, the insured pays the first \$250 or \$500 of each year's health care costs before the insurer begins paying) or **copayments** (that is, the insured pays, say, 20 percent of all health care costs and the insurance company pays 80 percent).

As discussed in Chapter 23, Medicare is a nationwide federal health care program available to Social Security beneficiaries and persons with disabilities. One part of Medicare is a hospital insurance program that, after a deductible of \$1,100 in 2010, covers all reasonable costs for the first 60 days of inpatient care per "benefit period" and lesser amounts (on a cost-sharing basis) for additional days. Coverage is also provided for posthospital nursing services, home health care, and hospice care for the terminally ill. Other parts of Medicare

(including insurance programs for physicians' services, laboratory and other diagnostic tests, outpatient hospital services, and prescription drugs) are voluntary but heavily subsidized by government. The monthly premiums that most participants pay cover about one-fourth of the cost of the benefits provided.

Medicaid provides payment for medical benefits to certain low-income people, including the elderly, the blind, persons with disabilities, children, and adults with dependent children. Those who qualify for Temporary Aid for Needy Families (TANF) and the Supplemental Security Income (SSI) program are automatically eligible for Medicaid. Nevertheless, Medicaid covers less than half of those living in poverty. The federal government and the states share the cost of Medicaid. On average, the states fund 40 percent and the federal government 60 percent of each Medicaid dollar spent.

Overall, about 21 percent of each dollar spent on health care is financed by direct out-of-pocket payments by individuals. The fact that most U.S. health care is paid for by private insurance companies or the government is an important contributor to rising health care costs.

Percentage of GDP Figure 24.2 shows how U.S. health care spending has been increasing as a percentage of GDP. Health care spending absorbed 5.2 percent of GDP in 1960 but rose to 17.5 percent in 2014.

International Comparisons Global Perspective 24.1 reveals that among the industrialized nations, health care spending as a percentage of GDP is highest in the United States. It is reasonable to assume that health care spending varies positively with output and incomes, but that doesn't account for the higher U.S. health expenditures as a percentage of GDP. Later

in the chapter we discuss various explanations for why the United States is “in a league of its own” as to its proportion of output devoted to health care.

Quality of Care: Are We Healthier?

To compare the quality of health care from country to country is difficult. Yet there is general agreement that medical care (although not health and not “preventive treatment”) in the United States is among the best in the world. Average life expectancy in the United States has increased by about 7 years since 1970, and U.S. physicians and hospitals employ the most advanced medical equipment and technologies. Also, more than half the world’s medical research funding is done in the United States. As a result, the incidence of disease has been declining and the quality of treatment has been improving. Polio has been virtually eliminated, ulcers are successfully treated without surgery, angioplasty and coronary bypass surgery greatly benefit those with heart disease, sophisticated body scanners are increasingly available diagnostic tools, and organ transplants and prosthetic joint replacements are more and more common.

That is the good news. But there is other news as well. Despite new screening and treatment technologies, the breast cancer mortality rate has shown only modest improvement. Tuberculosis, a virtually forgotten disease, has reappeared. The AIDS epidemic has claimed more than 658,000 American lives. More generally, some experts say that high levels of health care spending have not produced significantly

better health and well-being. U.S. health care expenditures are the highest in the world absolutely, as a proportion of GDP, and on a per capita basis. Yet many nations have lower rates of maternal and infant mortality and longer life expectancies.

Economic Implications of Rising Costs

L024.2 Relate the economic implications of rising health care costs.

The most visible economic effects of rising health care costs are higher health insurance premiums to employers and higher out-of-pocket costs to workers. But rising health care costs have other economic effects as well.

Reduced Access to Care

Higher health care costs and insurance premiums reduce access to health care. Some employers reduce or eliminate health insurance as part of their pay packages and some uninsured workers go without private health insurance. Consequently, the number of uninsured grows. We will consider this issue in detail momentarily.

Labor Market Effects

Surging health care costs have three main effects on labor markets:

- **Slower wage growth** First, gains in workers' total compensation (wages plus fringe benefits, including health insurance paid for by employers) generally match gains in productivity. When health care costs (and thus insurance prices) rise more rapidly than productivity, firms wanting to maintain the existing level of health care benefits for their workers must reduce the growth of the wage portion of the total compensation package. Thus, in the long run, workers bear the burden of rising health care costs in the form of slower-growing wages.
- **Use of part-time and temporary workers** The high cost of employer-provided health insurance has led some employers to restructure their workforces: Full-time workers with health insurance benefits are employed in smaller numbers, and uninsured part-time or temporary workers are employed in greater numbers. Similarly, an employer with a generous but expensive health care plan might reduce its health insurance expense by discharging its insured lower-wage workers—janitors, gardeners, and cafeteria staff—and replacing them with workers employed by outside independent contractors that provide little or no health insurance for their employees.
- **Outsourcing (and offshoring)** Burdened by rising insurance costs, some firms may find it profitable to shift part of their production to outside suppliers that may be either domestic or international. This outsourcing may lower labor costs in situations where the outside suppliers provide fewer medical benefits to their workers. Offshoring (international outsourcing) has shifted jobs to developing economies such as Mexico, India, and China. Although labor productivity in these countries is considerably lower than that in the United States, lower wages and employer-provided medical benefits may be sufficient to make offshoring profitable. Rising domestic medical expenses therefore may join a host of other factors, including shifts in comparative advantage, in encouraging this practice.

Personal Bankruptcies

Large, uninsured medical bills are one of the major causes of personal bankruptcy. Health care experts point out that medical bills are often the last to be paid because unlike other bills there is nothing to repossess, shut off, or foreclose. So medical bills sometimes build up beyond the point of a realistic means for full repayment. Even individuals who pay all bills in a timely fashion can find themselves in tremendous financial difficulty when they face large, uninsured medical bills

for major operations (such as open-heart surgery) and expensive medical procedures (such as cancer treatment).

Impact on Government Budgets

The budgets of federal, state, and local governments are negatively affected by spiraling and sometimes unpredictable health care expenditures. In the past two decades, spending for health care through Medicare and Medicaid has been by far the fastest-growing segment of the federal budget. To cover those rising expenditures, the government must either raise taxes or reduce the portion of the budget used for national defense, education, environmental programs, scientific research, and other spending categories.

The states are also finding it difficult to cover their share of the Medicaid bill. Most of them have been forced to raise their tax rates and search for new sources of revenue, and many of them have had to reduce spending on nonhealth programs such as infrastructure maintenance, welfare, and education. Local governments face similar budget strains in trying to finance public health services, hospitals, and clinics.

Too Much Spending?

Increased spending on computers or houses would be a sign of prosperity, not a cause for alarm, because society is obtaining more of each. What is different about increased spending on health care? Maybe nothing, say some economists. William Nordhaus of Yale, for example, estimated that the economic value of increases in longevity over the last 100 years nearly equals the total value of the additional GDP produced during that period. According to Kevin Murphy and Robert Topel, economists at the University of Chicago, reduced mortality from heart disease alone contributes \$1.5 trillion of benefits a year in the United States. That nearly equals the entire annual GDP of Canada.

While all economists agree that improved health care has greatly contributed to society's GDP and well-being, many economists think that health care expenditures in the United States are inefficiently large. The production of health care requires scarce resources such as capital in the form of hospitals and diagnostic equipment and the highly skilled labor of physicians, technicians, and nurses. The total output of health care in the United States may be so large that health care, at the margin, is worth less than the alternative goods and services these resources could otherwise have produced. The United States therefore may be consuming health care beyond the $MB = MC$ point that defines efficiency.

If resources are overallocated to health care, society incurs an efficiency loss. Resources used excessively in health care could be used more productively to build new factories, support research and development, construct new bridges and roads, support education, improve the environment, or provide more consumer goods.

The suggested “too much of a good thing” results from peculiarities in the market for health care. We will see that the possibility of overspending arises from the way health care is financed, the asymmetry of information between consumers and providers, and the interaction of health insurance with technological progress in the industry.

Limited Access

L024.3 Discuss the problem of limited access to health care for those without insurance.

The other health care problem is limited access. Even though there may be an overallocation of resources to health care, not all Americans can obtain the health care they need. Extrapolations from government surveys indicate that in 2015 about 30 million Americans, or roughly 9 percent of the population, had no health insurance for the entire year. As health care costs (and therefore health care insurance premiums) continue to rise, the number of uninsured could grow.

Who are the medically uninsured? As incomes rise, so does the probability of being insured. So it is no surprise that the uninsured are concentrated among the poor. Medicaid is designed to provide health care for the poor who are on welfare. But many poor people work at low or minimum-wage jobs without health care benefits, earning “too much” to qualify for Medicaid yet not enough to afford private health insurance. About half of the uninsured have a family head who works full time. Many single-parent families, African Americans, and Hispanics are uninsured simply because they are more likely to be poor.

Curiously, those with excellent health and those with the poorest health also tend to be uninsured. Many young people with excellent health simply choose not to buy health insurance. The chronically ill find it very difficult and too costly to obtain insurance because of the likelihood that they will incur substantial health care costs in the future. Because private health insurance is most frequently obtained through an employer, the unemployed are also likely to lack insurance.

Workers for smaller firms are also less likely to have health insurance. The main reason is that administrative expenses for a small firm may be 30 to 40 percent of insurance premiums, as opposed to only 10 percent for a large firm. Also, corporations can deduct health insurance premiums from income to obtain substantial tax savings. Small unincorporated businesses can deduct only part of their health insurance expenses.

Low-wage workers are also less likely to be insured. Earlier we noted that in the long run employers pass on the increasing expense of health care insurance to workers as lower wages. This option is not available to employers who are paying the minimum wage. Thus as health care insurance premiums rise, employers cut or eliminate this benefit from the compensation package for their minimum- and low-wage workers. As a result, these workers are typically uninsured.

Although many of the uninsured forgo health care, some do not. A few are able to pay for it out of pocket. Others may wait until their illness reaches a critical stage and then go to a hospital for admittance or to be treated in the emergency room. This form of treatment is more costly than if the patient had insurance and therefore had been treated earlier by a physician. It is estimated that hospitals provide about \$40 billion of uncompensated (“free”) health care per year. The hospitals then try to shift these costs to those who have insurance or who can pay out of pocket.

QUICK REVIEW 24.1

- ✓ Private, employer-funded health insurance plays a much larger role in the delivery of health care in the United States than it does in other countries.
- ✓ Health care spending in the United States has been increasing absolutely and as a percentage of gross domestic output.
- ✓ Rising health care costs have caused (a) more people to find health insurance unaffordable; (b) adverse labor market effects, including slower real-wage growth and increased use of part-time and temporary workers; and (c) restriction of nonhealth spending by governments.
- ✓ Rising health care spending may reflect an overallocation of resources to the health care industry.
- ✓ Approximately 9 percent of all Americans have no health insurance and, hence, inferior access to quality health care.

Why the Rapid Rise in Costs?

L024.4 List the demand and supply factors explaining rising health care costs.

The rising prices, quantities, and costs of health care services are the result of the demand for health care increasing much more rapidly than supply. We will examine the reasons for this in some detail. But first it will be helpful to understand certain characteristics of the health care market.

Peculiarities of the Health Care Market

We know that purely competitive markets achieve both allocative and productive efficiency: The most desired products are produced in the least costly way. We also have found that many imperfectly competitive markets, perhaps aided by regulation or the threat of antitrust action, provide outcomes generally accepted as efficient. What, then, are the special features of the health care market that have contributed to rising prices and thus escalating costs to buyers?

- **Ethical and equity considerations** Ethical questions inevitably intervene in markets when decisions involve

the quality of life, or literally life or death. Although we might not consider it immoral or unfair if a person cannot buy a Mercedes or a personal computer, society regards it as unjust for people to be denied access to basic health care or even to the best available health care. In general, society regards health care as an “entitlement” or a “right” and is reluctant to ration it solely by price and income.

- **Asymmetric information** Health care buyers typically have little or no understanding of complex diagnostic and treatment procedures, while the physicians, who are the health care sellers of those procedures, possess detailed information. This creates the unusual situation in which the doctor (supplier) as the agent of the patient (consumer) tells the patient what health care services he or she should consume. We will say more about this shortly.
- **Positive externalities** The medical care market often generates positive externalities (spillover benefits). For example, an immunization against polio, smallpox, or measles benefits the immediate purchaser, but it also benefits society because it reduces the risk that other members of society will be infected with a highly contagious disease. Similarly, a healthy labor force is more productive, contributing to the general prosperity and well-being of society.
- **Third-party payments: insurance** Because four-fifths of all health care expenses are paid through public or private insurance, health care consumers pay much lower out-of-pocket “prices” than they would otherwise. Those lower prices are a distortion that results in “excess” consumption of health care services.

The Increasing Demand for Health Care

With these four features in mind, let’s consider some factors that have increased the demand for health care over time.

Rising Incomes: The Role of Elasticities Because health care is a normal good, increases in domestic income have caused increases in the demand for health care. While there is some disagreement as to the exact income elasticity of demand for health care, several studies for industrially advanced countries suggest that the income elasticity coefficient is about 1. This means that per capita health care spending rises approximately in proportion to increases in per capita income. For example, a 3 percent increase in income will generate a 3 percent increase in health care expenditures. Some evidence suggests that income elasticity may be higher in the United States, perhaps as high as 1.5.

Estimates of the price elasticity of demand for health care imply that it is quite inelastic, with this coefficient being as low as 0.2. This means that the quantity of health care consumed

declines relatively little as price increases. For example, a 10 percent increase in price would reduce quantity demanded by only 2 percent. An important consequence is that total health care spending will increase as the price of health care rises.

The relative insensitivity of health care spending to price changes results from four factors. First, people consider health care a necessity, not a luxury. Few, if any, good substitutes exist for medical care in treating injuries and infections and alleviating various ailments. Second, medical treatment is often provided in an emergency situation in which price considerations are secondary or irrelevant. Third, most consumers prefer a long-term relationship with their doctors and therefore do not “shop around” when health care prices rise. Fourth, most patients have insurance and are therefore not directly affected by the price of health care. If insured patients pay, for example, only 20 percent of their health care expenses, they are less concerned with price increases or price differences between hospitals and between doctors than they would be if they paid 100 percent themselves.

An Aging Population The U.S. population is aging. People 65 years of age and older constituted approximately 9 percent of the population in 1960 but 14 percent in 2014. Projections for the year 2030 indicate 19 percent of the population will be 65 or over by that year.

This aging of the population affects the demand for health care because older people encounter more frequent and more prolonged spells of illness. Specifically, those 65 and older consume about three and one-half times as much health care as those between 19 and 64. In turn, people over 84 consume almost two and one-half times as much health care as those in the 65 to 69 age group. Health care expenditures are often extraordinarily high in the last year of one’s life.

In 2011 the oldest of the 76 million members of the baby boom generation born between 1946 and 1964 began turning 65. We can expect that fact to create a substantial surge in the demand for health care.

Unhealthy Lifestyles Substance abuse helps drive up health care costs. The abuse of alcohol, tobacco, and illicit drugs damages health and is therefore an important component of the demand for health care services. Alcohol is a major cause of injury-producing traffic accidents and liver disease. Tobacco use markedly increases the probability of cancer, heart disease, bronchitis, and emphysema. Illicit drugs are a major contributor to violent crime, health problems in infants, and the spread of AIDS. In addition, illicit-drug users make hundreds of thousands of costly visits to hospital emergency rooms each year. And overeating and lack of exercise contribute to heart disease, diabetes, and many other ailments. One study estimated that obesity-related medical conditions may account for 21 percent of all U.S. medical spending.

The Role of Doctors Physicians may increase the demand for health care in several ways.

Supplier-Induced Demand As we mentioned before, doctors, the suppliers of medical services, have much more information about those services than consumers, who are the demanders. While a patient might be well informed about food products or more complex products such as cameras, he or she is not likely to be well informed about diagnostic tests such as magnetic resonance imaging or medical procedures such as joint replacements. Because of this asymmetric information (informational imbalance), a principal-agent problem emerges: The supplier, not the demander, decides what types and amounts of health care are to be consumed. This situation creates a possibility of “supplier-induced demand.”

This possibility becomes especially relevant when doctors are paid on a **fee-for-service** basis, that is, paid separately for each service they perform. In light of the asymmetric information and fee-for-service arrangement, doctors have an opportunity and an incentive to suggest more health care services than are absolutely necessary (just as an auto repair shop has an opportunity and an incentive to recommend replacement of parts that are worn but still working).

More surgery is performed in the United States, where many doctors are paid a fee for each operation, than in foreign countries, where doctors are often paid fixed salaries unrelated to the number of operations they perform. Furthermore, doctors who own X-ray or ultrasound machines do four times as many tests as doctors who refer their patients to radiologists. More generally, studies suggest that up to one-third of common medical tests and procedures are either inappropriate or of questionable value.

The seller’s control over consumption decisions has another result: It eliminates much of the power buyers might have in controlling the growth of health care prices and spending.

Defensive Medicine “Become a doctor and support a lawyer,” says a bumper sticker. The number of medical malpractice lawsuits admittedly is high. To a medical doctor, each patient represents not only a person in need but also a possible malpractice suit. As a result, physicians tend to practice **defensive medicine**. They recommend more tests and procedures than are warranted medically or economically to protect themselves against malpractice suits.

Medical Ethics Medical ethics may drive up the demand for health care in two ways. First, doctors are legally and ethically committed to using “best-practice” techniques in serving their patients. This often means the use of costly medical procedures that may be of only slight benefit to patients.

Second, public values seem to support the medical ethic that human life should be sustained as long as possible. This makes it difficult to confront the notion that health care is

Why Do Hospitals Sometimes Charge \$25 for an Aspirin?

To save taxpayers money, Medicare and Medicaid set their payment rates for

medical services above marginal cost but below average total cost. Doing so gives health care providers an incentive to provide services to Medicare and Medicaid patients because $MR > MC$. But it also means that government health insurance programs are not reimbursing the full cost of treating Medicare and Medicaid patients. In particular, the programs are not picking up their share of the fixed costs associated with providing health care.

As an example, consider an elderly person who uses Medicare. If he gets into a car accident and is taken to the local emergency room, the hospital will run up a wide variety of marginal costs, including ambulance charges, X-rays, medications, and the time of the nurses and doctors who help him. But the hospital also has a wide variety of fixed costs including rent, utility bills, computer networks, and lots of hideously expensive medical equipment.

These costs have to be borne by somebody. So when Medicare and Medicaid fail to pay their full share of the fixed costs, other patients must pick up the slack. The result has been for hospitals to transfer as much as possible of the fixed costs onto patients with private health insurance. The hospitals overbill private insurance companies so as to make up for the fixed costs that the government refuses to pay.

That is why you will hear stories about hospitals charging patients with private insurance \$25 for a single aspirin or \$100 for a newborn baby’s first pair of diapers. They are making up for the fact that hospitals around the country lost over \$51 billion in 2014 because Medicare and Medicaid on average only reimbursed hospitals about 90 percent of the total cost of providing medical services to Medicare and Medicaid patients.

provided with scarce resources and therefore must be rationed like any other good. Can society afford to provide \$5,000-per-day intensive care to a comatose patient unlikely to be restored to reasonable health? Public priorities seem to indicate that such care should be provided, and those values again increase the demand for health care.

Role of Health Insurance

As we noted in Figure 24.1, 79 percent of health care spending is done not by health care consumers through direct

out-of-pocket payments but by private health insurance companies or by the government through Medicare and Medicaid.

Individuals and families face potentially devastating monetary losses from a variety of hazards. Your house may burn down, you may be in an auto accident, or you may suffer a serious illness. An insurance program is a means of protection against the huge monetary losses that can result from such hazards. A number of people agree to pay certain amounts (premiums) periodically in return for the guarantee that they will be compensated if they should incur a particular misfortune. Insurance is a means of paying a relatively small known cost in exchange for obtaining protection against an uncertain but potentially much larger cost.

This financial arrangement can be highly advantageous to those purchasing insurance, but it also alters incentives in ways that can contribute to rising costs and the overconsumption of health care.

The Moral Hazard Problem The moral hazard problem is the tendency of one party to an agreement to alter her or his behavior in a way that is costly to the other party. Health care insurance can change behavior in two ways. First, some insured people may be less careful about their health, taking fewer steps to prevent accident or illness. Second, insured individuals have greater incentives to use health care more intensively than they would if they did not have insurance. Let's consider both aspects of moral hazard.

Less Prevention Health insurance may increase the demand for health care by encouraging behaviors that require more health care. Although most people with health care insurance are probably as careful about their health as are those without insurance, some may be more inclined to smoke, avoid exercise, and eat unhealthful foods, knowing they have insurance. Similarly, some individuals may take up ski jumping or rodeo bull riding if they have insurance covering the costs of orthopedic surgeons. And if their insurance covers rehabilitation programs, some people may be more inclined to experiment with alcohol or drugs.

Overconsumption Insured people go to doctors more often and request more diagnostic tests and more complex treatments than they would if they were uninsured because, with health insurance, the price or opportunity cost of consuming health care is minimal. For example, many individuals with private insurance pay a fixed premium for coverage, and beyond that, aside from a modest deductible, their health care is “free.” This situation differs from most markets, in which the price to the consumer reflects the full opportunity cost of each unit of the good or service. In all markets, price provides a direct economic incentive to restrict use of the product. The minimal direct price to the insured consumer of health care, in contrast, creates an incentive to overuse the health care system. Of course, the penalty for overuse will ultimately show up in higher insurance premiums, but all policyholders will

share those premiums. The cost increase for the individual health consumer will be relatively small.

Also, the availability of insurance removes the consumer's budget constraint (spending limitation) when he or she decides to consume health care. Recall from Chapter 7 that budget constraints limit the purchases of most products. But insured patients face minimal or no out-of-pocket expenditures at the time they purchase health care. Because affordability is not the issue, health care may be overconsumed.

Government Tax Subsidy Federal tax policy toward employer-financed health insurance works as a **tax subsidy** that strengthens the demand for health care services. Specifically, employees do not pay federal income or payroll tax (Social Security) on the value of the health insurance they receive as an employee benefit. Employees thus request and receive more of their total compensation as nontaxed health care benefits and less in taxed wages and salaries.

The government rationale for this tax treatment is that positive spillover benefits are associated with having a healthy, productive workforce. So it is appropriate to encourage health insurance for workers. The tax break does enable more of the population to have health insurance, but it also contributes to greater consumption of health care. Combined with other factors, the tax break may result in an overconsumption of health care.

To illustrate: If the marginal tax rate is, say, 28 percent, \$1 worth of health insurance is equivalent to 72 cents in after-tax pay. Because the worker can get more insurance for \$1 than for 72 cents, the exclusion of health insurance from taxation increases purchases of health insurance, thus increasing the demand for health care. In essence, the 28-cent difference acts as a government subsidy to health care. One estimate suggests that this subsidy costs the federal government \$120 billion per year in forgone tax revenue and boosts private health insurance spending by about one-third. Actual health care spending may be 10 to 20 percent higher than otherwise because of the subsidy.

Graphical Portrayal A simple demand and supply model illustrates the effect of health insurance on the health care market. Figure 24.3a depicts a competitive market for health care services; curve D shows the demand for health care services if all consumers are uninsured, and S represents the supply of health care. At market price P_a the equilibrium quantity of health care is Q_a .

Recall from our discussion of competitive markets that output Q_a results in allocative efficiency, which means there is no better alternative use for the resources allocated to producing that level of health care. To see what we mean by “no better use,” recall that:

- As we move down along demand curve D , each succeeding point indicates, via the price it represents, the marginal benefit that consumers receive from that unit.

FIGURE 24.3 Insurance and the overallocation of resources to health care. (a) Without health insurance, the optimal amount of health care consumed is Q_a , where the marginal benefit and marginal cost of health care are equal. (b) The availability of private and public insurance increases the demand for health care, as from D to D_i , and reduces the price to the consumer from P_a to P_c (here, equal to one-third of the full price P_b). This lower after-insurance price results in overconsumption (Q_c rather than Q_a). Area abc represents the efficiency loss (or deadweight loss) from the overallocation of resources to health care.

- The supply curve is the producers' marginal-cost curve. As we move up along supply curve S , each succeeding point indicates the marginal cost of each successive unit of health care.
- For each unit produced up to the equilibrium quantity Q_a , marginal benefit exceeds marginal cost (because points on D are above those on S). At Q_a marginal benefit equals marginal cost, designating allocative efficiency. No matter what else those resources could have produced, the greatest net benefit to society is obtained by using those resources to produce Q_a units of health care.

But allocative efficiency occurs only when consumers pay the full market price for a product, as is assumed in Figure 24.3a. What happens when we introduce health insurance that covers, say, two-thirds of all health care costs? In Figure 24.3b, with private or public health insurance in place, consumers increase their demand for health care, as from D to D_i . At each possible price they desire more health care than before because insurance will pick up a large part of the bill. Given the supply curve of health care S , this increase in demand raises the price of health care to P_b . But with the insurance, consumers pay only one-third of the new higher price. This is less than without the insurance because the new price is only P_c ($= \frac{1}{3}P_b$)—rather than the previous price P_a . So they increase their consumption of health care from Q_a to Q_c .

The added consumption (and production) of health care is inefficient. Between Q_a and Q_c each unit's marginal cost to society (measured on curve S) exceeds its marginal benefit (measured on before-insurance demand curve D). Each unit of health care between Q_a and Q_c is an overallocation of resources to health care. Area abc shows the efficiency loss (or deadweight loss) that results.

Figure 24.3b implies that a trade-off exists between efficiency and equity. Standards of fairness or equity in the United States lead people to believe that all citizens should have access to basic health care, which is why government created social insurance in the form of Medicare and

Medicaid. Also, it helps explain the federal tax subsidy to private health insurance, which again makes health care more accessible. The problem, as Figure 24.3b shows, is that the greater the availability of insurance (and thus the more equitable society makes access to health care), the greater the overallocation of resources to the health care industry. This overallocation would be even greater if health care were provided completely “free” under a program of national health insurance. Consumers would purchase health care as long as the marginal benefit to themselves as individuals was positive, regardless of the true cost to society.

Rationing to Control Costs We have just seen that by reducing the marginal costs facing patients, both private health insurance and government health insurance drive up prices. But then why is it that the United States, with its emphasis on private health insurance, spends so much more on health care than countries like the United Kingdom and Canada that provide national health insurance? If both types of insurance promote higher prices, why do we see higher health care spending in the United States than in those other countries?

One contributing factor is that the countries with national health insurance use various nonprice mechanisms to ration care. These mechanisms restrict the quantity of health care services supplied and, consequently, the amount of money spent providing health care.

Some nonprice rationing is done by committees of medical and budgetary experts. In the United Kingdom, for instance, the National Committee for Health and Clinical Excellence has set a general limit of £30,000 (approximately \$44,000) on the cost of extending life for a year. Applying this rule to a specific situation, if an anticancer treatment would cost more than £30,000 to extend a cancer patient's life for a year, the United Kingdom's national health service would not pay for it. This cost rule keeps a lid on expenditures.

Waiting is another nonprice mechanism that rations care in countries with national health insurance. In the Canadian system, patients often have waits of weeks, months, or even

years for certain diagnostic procedures and surgeries. This is the result of the Canadian government's effort to control expenditures by restricting hospitals' capital spending. To illustrate, there are only one-fifth as many magnetic resonance imaging (MRI) machines per million people in Canada as in the United States. This results in a substantial waiting list for MRI scans in Canada.

By contrast, private health insurers in the United States have not had to obey national committees that set spending limits. Nor have they had to answer to government budget officials attempting to control expenditures by restricting capital spending. Instead, private health insurers have faced a very different regulatory system that has tended to increase rather than decrease spending.

To see why this is true, note that until the Patient Protection and Affordable Care Act, private health insurers were regulated almost entirely at the state level. In addition, each state insurance regulator had very different incentives compared to the national health insurance regulators found in other countries.

In a country with national health insurance, regulators are confronted by their government's budget constraint and the fact that the government has a limited supply of tax dollars to spend on health care. As a result, they have a strong incentive to deny care and limit spending. By contrast, state insurance regulators in the United States did not have to worry about exhausting government budgets because private health insurance is paid for with private money rather than government money. This led to a tendency for state insurance regulators to focus on benefits more than costs.

To see why this happened, note that requiring insurance companies to cover more people or treat more conditions is politically popular, while requiring them to cut coverage to save money is politically unpopular. With many states having popularly elected state insurance commissioners and the rest having insurance commissioners appointed by either the governor or the legislature, there was constant political pressure for state insurance regulators to pass new regulations requiring insurance companies to spend more rather than less. States incrementally imposed various rules expanding the number of conditions that had to be covered by insurers as well as the amounts that insurers had to spend on patient care.

Because these requirements involved the costly provision of additional care, insurance companies responded by raising insurance premiums. Thus, America's state-based system of government insurance regulation tended to increase rather than decrease the amount spent on health care.

Many economists view this regulatory system as one of the factors that has contributed to the United States spending more of its GDP on health care than any other nation on earth. While regulators in other countries have sought out ways to deny care and reduce costs, state regulators in America have tended to mandate that insurance companies expand treatment and incur additional costs.

As we will discuss later, the Patient Protection and Affordable Care Act creates a new set of federal insurance regulators that will largely supersede state insurance regulators. Part of the controversy related to the bill is whether the new federal regulators might eventually be tasked with denying care in the way that European regulators have.

Supply Factors in Rising Health Care Prices

Supply factors have also played a role in rising health care prices. Specifically, the supply of health care services has increased, but more slowly than demand. A combination of factors has produced this relatively slow growth of supply.

Supply of Physicians The supply of physicians in the United States has increased over the years; in 1975 there were 169 physicians per 100,000 people; by 2011 there were 245. But this increase in supply has not kept up with the increase in the demand for physicians' services. As a result, physicians' fees and incomes have increased more rapidly than average prices and incomes for the economy as a whole.

Conventional wisdom has been that physician groups, for example, the American Medical Association, have purposely kept admissions to medical schools, and therefore the supply of doctors, artificially low. But that is too simplistic. A rapidly rising cost of medical education seems to be the main cause of the relatively slow growth of doctor supply. Medical training requires 4 years of college, 4 years of medical school, an internship, and perhaps 3 or 4 years of training in a medical specialty. The opportunity cost of this education has increased because the salaries of similarly capable people have soared in other professions. The direct expenses have also increased, largely due to the increasingly sophisticated levels of medical care and therefore of medical training.

High and rising education and training costs have necessitated high and rising doctors' fees to ensure an adequate return on this sort of investment in human capital. Physicians' incomes are indeed high, averaging in 2015 from about \$195,000 for family care physicians up to \$541,000 for neurosurgeons. But the costs of obtaining the skills necessary to become a physician are also very high. Data show that while doctors have high rates of return on their educational expenses, those returns are below the returns for the holders of masters of business administration degrees.

Slow Productivity Growth Productivity growth in an industry tends to reduce costs and increase supply. In the health care industry, such productivity growth has been modest. One reason is that health care is a service, and it is generally more difficult to increase productivity for services than for goods. It is relatively easy to increase productivity in manufacturing by mechanizing the production process. With more and better machinery, the same number of workers can produce greater

output. But services often are a different matter. It is not easy, for example, to mechanize haircuts, child care, and pizza delivery. How do you significantly increase the productivity of physicians, nurses, and home care providers?

Also, competition for patients among many providers of health care has not been sufficiently brisk to force them to look for ways to reduce costs by increasing productivity. When buying most goods, customers typically shop around for the lowest price. This shopping requires that sellers keep their prices low and look to productivity increases to maintain or expand their profits. But patients rarely shop for the lowest prices when seeking medical care. In fact, a patient may feel uncomfortable about being operated on by a physician who charges the lowest price. Moreover, if insurance pays for the surgery, there is no reason to consider price at all. The point is that unusual features of the market for health care limit competitive pricing and thus reduce incentives to achieve cost saving via advances in productivity.

Changes in Medical Technology Some technological advances in medicine have lowered costs. For example, the development of vaccines for polio, smallpox, and measles has greatly reduced health care expenditures for the treatment of those diseases. And reduced lengths of stays in hospitals have lowered the costs of medical care.

But many medical technologies developed since the Second World War have significantly increased the cost of medical care either by increasing prices or by extending procedures to a greater number of people. For example, because they give more accurate information, advanced body scanners costing up to \$1,000 per scan are often used in place of X-rays that cost less than \$100 for each scan. Desiring to offer the highest quality of service, hospitals want to use the very latest equipment and procedures. These newer, more expensive treatments are believed to be more effective than older ones. But doctors and hospital administrators both realize that the high fixed cost of such equipment means it must be used extensively to reduce the average cost per patient and recoup the investment at “fair return” charges per procedure.

As another example, organ transplants are extremely costly. Before the development of this technology, a person with a serious liver malfunction died. Now a liver transplant can cost \$200,000 or more, with subsequent medical attention costing \$10,000 to \$20,000 per year for the rest of the patient’s life.

Finally, consider new prescription medications. Pharmaceutical companies have developed very expensive drugs that often replace less expensive ones and are prescribed for a much wider range of physical and mental illnesses. Although these remarkable new medications greatly improve health care, they also contribute to rising health care costs.

The historical willingness of private and public insurance to pay for new treatments without regard to price and

Electronic Medical Records

The Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 provides \$20 billion of subsidies to encourage hospitals and physicians to adopt electronic medical records.

The subsidies are designed to get doctors and nurses to switch from traditional paper records to electronic databases. That way, hospital administrators should be able to easily search for instances where costs might be cut. They could, for instance, notice whether doctors are overprescribing certain medications or scheduling expensive MRI scans when less-expensive X-rays would suffice.

Unfortunately, these systems seem to raise costs and lower the quality of care. When records are done with pen and paper, doctors only write down the information they think is relevant. By contrast, electronic systems demand that during every appointment, the doctor fill out every single item from a comprehensive list of questions and drop-down menus. That is wasteful because the vast majority of those items are going to be totally irrelevant for any particular patient. The systems are so time-intensive that many doctors report that they are now seeing fewer patients because it takes so long to fill out the forms.

At the same time, insurance billings have gone up because hospitals using electronic systems now have a comprehensive record of *everything* that was discussed at each appointment. Armed with that information, they are billing insurance companies and Medicare and Medicaid for many more procedures than was the case when records were kept by hand and doctors only wrote down the most important information about each patient.

The projected efficiency gains from being able to search for patterns of overuse have not materialized because the financial incentive for each hospital is not to look for patterns of overuse but, instead, to bill for every little thing that it can. As a result, care is down while costs are up.

number of patients has contributed to the incentive to develop and use new technologies. Insurers, in effect, have encouraged research into and development of health care technologies, regardless of their cost. Recently, when insurance companies resisted paying for new expensive treatments such as bone marrow transplants, public outcries led them to change their minds. So expanding insurance coverage leads to new, often more expensive medical technologies,

which in turn lead to a demand for a wider definition of what should be covered by insurance.

Relative Importance

According to most analysts, the demand and supply factors we have discussed vary in their impact on escalating health care costs. As we noted, the income elasticity of demand for health care is estimated to be upward of 1.5 in the United States, meaning that increased income brings with it more-than-proportionate increases in health care spending. But rising income does not alone explain the rocketing increase in health care spending as a percentage of total domestic output (income). Furthermore, government studies estimate that the aging population accounts for less than 10 percent of the current increase in per capita health care spending.

Most experts attribute the relative rise in health care spending to (1) advances in medical technology, combined with (2) the medical ethic of providing the best treatment available, (3) private and public health insurance, and (4) fee-for-service physicians' payments by health insurance firms. Through technological progress, great strides have been made in the diagnosis, treatment, and prevention of illness. But the third-party (insurance) payment system provides little incentive to limit the development or use of such technologies because it has no mechanism to force an equating of marginal costs and marginal benefits. And the "best treatment available" ethic, together with the fee-for-service payment system, ensures that any new technology with a positive marginal benefit will get used and be billed for, regardless of the marginal cost to society.

QUICK REVIEW 24.2

- ✓ Characteristics of the health care market are (a) the widespread view of health care as a "right," (b) asymmetric information between consumers and suppliers, (c) the presence of positive externalities, and (d) payment mostly by insurance.
- ✓ The demand for health care has increased for many reasons, including rising incomes, an aging population, unhealthy lifestyles, the role of doctors as advisers to patients, the practice of defensive medicine, and a fee-for-service payment system via health insurance.
- ✓ Countries with national health insurance systems contain costs by denying care for certain procedures and by limiting capital expenditures.
- ✓ The supply of health care has grown slowly, primarily because of (a) relatively slow productivity growth in the health care industry, (b) rising costs of medical education and training, and (c) greater use of very-high-cost health care technologies.

Cost Containment: Altering Incentives

LO24.5 Describe the cost-containment strategies that rely on altering the financial incentives facing either patients or health service providers.

The Patient Protection and Affordable Care Act is the latest in a long series of attempts to control the growth of health care costs, prices, and spending. Many of these efforts have been focused on reducing the incentives to overconsume health care.

Deductibles and Copayments

Insurance companies have reacted to rising health care costs by imposing sizable deductibles and copayments on those they insure. Instead of covering all of an insured's medical costs, a policy might now specify that the insured pay the first \$250 or \$500 of each year's health care costs (the deductible) and 15 or 20 percent of all additional costs (the copayment). The deductible and copayment are intended to alleviate the overuse problem by creating a direct payment and therefore an opportunity cost to the health care consumer. The deductible has the added advantage of reducing the administrative costs of insurance companies in processing many small claims.

Health Savings Accounts

A federal law enacted in 2003 established **health savings accounts (HSAs)**. These accounts are available to all workers who are covered by health insurance plans with annual deductibles of \$1,000 or more and do not have other first-dollar insurance coverage. Individuals can make tax-deductible contributions into their HSAs, even if they do not itemize deductions on their tax forms. Employers can also make tax-free contributions to workers' accounts if they choose. Earnings on the funds in HSAs are not taxable, and the owners of these accounts can use them to pay for approved medical expenses. Unused funds in HSAs accumulate and remain available for later out-of-pocket medical expenses. Account holders can place additional money into their accounts each year between age 55 and the year they become eligible for Medicare.

HSAs are designed to promote personal saving out of which workers can pay routine health care expenses while working and Medicare copayments and deductibles later, during retirement. HSAs are also designed to reduce escalating medical expenses by injecting an element of competition into health care delivery. Because individuals are using some of their own HSA money to pay for health care, they presumably will assess their personal marginal costs and marginal benefits in choosing how much and what type of health care to obtain. They will also have a strong incentive to inquire about and compare prices charged by various qualified medical providers. Holders of HSAs never lose their accumulated funds. They can

remove money for nonmedical purchases but must pay income taxes and a 10 percent penalty on such withdrawals.

Managed Care

Managed-care organizations (or systems) are those in which medical services are controlled or coordinated by insurance companies or health care organizations to reduce health care expenditures. In 2009 nearly 90 percent of all U.S. workers received health care through such “managed care.” These organizations are of two main types.

Some insurance companies have set up **preferred provider organizations (PPOs)**, which require that hospitals and physicians accept discounted prices for their services as a condition for being included in the insurance plan. The policyholder receives a list of participating hospitals and doctors and is given, say, 80 to 100 percent reimbursement of health care costs when treated by PPO physicians and hospitals. If a patient chooses a doctor or hospital outside the PPO, the insurance company reimburses only 60 to 70 percent. In return for being included as a PPO provider, doctors and hospitals agree to rates set by the insurance company for each service. Because these fees are less than those usually charged, PPOs reduce health insurance premiums and health care expenditures.

Many Americans now receive their medical care from **health maintenance organizations (HMOs)**, which provide health care services to a specific group of enrollees in exchange for a set annual fee per enrollee. HMOs employ their own physicians and contract for specialized services with outside providers and hospitals. They then contract with firms or government units to provide medical care for their workers, who thereby become HMO members. Because HMOs have fixed annual revenue, they may lose money if they provide “too much” care. So they have an incentive to hold down costs. They also have an incentive to provide preventive care in order to reduce the potentially far larger expense of corrective care.

Both PPOs and HMOs are managed-care organizations because medical use and spending are “managed” by closely monitoring physicians’ and hospitals’ behavior. The purpose of close monitoring is to eliminate unnecessary tests and treatments. Doctors in managed-care organizations might not order an MRI scan or an ultrasound test or suggest surgery because their work is monitored and because they may have a fixed budget. In contrast, an independent fee-for-service physician facing little or no oversight may have a financial incentive to order the test or do the surgery. Doctors and hospitals in a managed-care organization often share in an “incentive pool” of funds when they meet their cost-control goals.

The advantages of managed-care plans are that they provide health care at lower prices than traditional insurance and emphasize preventive medicine. The disadvantages are that the patient usually is restricted to physicians employed by or under contract with the managed-care plan. Also, some say that the focus on reducing costs has gone too far, resulting in

denial of highly expensive, but effective, treatment. This “too far” criticism was mainly leveled at HMOs, where incentives to reduce costs were the greatest. Perhaps because of a backlash against HMOs, firms have increasingly shifted workers from managed care toward PPOs.

Medicare and DRG

In 1983 the federal government altered the way it makes payments for hospital services received by Medicare patients. Rather than automatically paying all costs related to a patient’s treatment and length of hospital stay, Medicare authorized payments based on a **diagnosis-related group (DRG) system**. Under DRG, a hospital receives a fixed payment for treating each patient; that payment is an amount associated with the diagnosis—one of several hundred carefully detailed diagnostic categories—that best characterizes the patient’s condition and needs.

DRG payments obviously give hospitals the incentive to restrict the amount of resources used in treating patients. It is no surprise that under DRG the length of hospital stays has fallen sharply and more patients are treated on an outpatient basis. Critics, however, argue that this is evidence of diminished health care quality.

Limits on Malpractice Awards

Congress has, for many years, debated whether to cap (at, say, \$250,000 or \$500,000) the “pain and suffering” awards on medical malpractice lawsuits against physicians. Those who support malpractice caps say that patients should receive full compensation for economic losses but not be made wealthy through huge jury awards. They contend that capping the awards will reduce medical malpractice premiums and therefore lower health care costs. Opponents of caps counter that large “pain and suffering” awards deter medical malpractice. If so, such awards improve the overall quality of the health care system. Opponents also point out that malpractice awards are a negligible percentage of total health care costs. Thirty-three states have placed caps on the “pain and suffering” portion of malpractice awards.

QUICK REVIEW 24.3

- ✓ Policymakers have pursued several strategies when attempting to contain health care spending and prices.
- ✓ Insurance deductibles and copayments confront consumers with opportunity costs; managed-care organizations attempt to restrict their members’ use of health services; the diagnosis-related group (DRG) system caps the amount Medicare will spend on any procedure; and health savings accounts (HSAs) confront individuals with the marginal cost of routine health care expenses.

The Patient Protection and Affordable Care Act

L024.6 Summarize the goals of the Patient Protection and Affordable Care Act and the major changes that it institutes.

The primary goal of the Patient Protection and Affordable Care Act (PPACA) passed in 2010 was not cost containment but rather the extension of health insurance coverage to all Americans. In truth, covering every single citizen would have been possible only if America had moved to a national health insurance system similar to that used in Canada. Such a move would have been impossible politically, however, because opinion polls indicated that 75 percent of Americans with employer-provided health insurance rated their coverage as good or very good.

Thus, President Obama and like-minded members of Congress did not pursue the creation of a national health insurance system. Rather, they moved to extend and expand the existing system in which nearly all Americans receive their health care through either employer-provided health insurance or government-provided health insurance (Medicaid and Medicare). In promoting the PPACA, the president reassured audiences by telling them, “If you like your health care plan, you can keep it.”

Major Provisions

The authors of the PPACA understood that extending insurance coverage to millions of previously uninsured people would be costly. As with any group of people enrolled in a health insurance program, many would eventually become sick and need costly treatments. This problem was exacerbated by the fact that many of those without insurance were known to suffer from extremely costly medical conditions. These individuals were without insurance coverage precisely because private insurance companies (which have to either break even or go bankrupt) considered them to be too expensive to insure. Thus, if those with costly medical conditions were to be covered, significant new revenue sources would have had to be found.

The PPACA aimed to obtain the needed revenue from two main sources: a personal mandate to buy insurance and an assortment of other new taxes. We will discuss each as we go over the PPACA’s major provisions.

Preexisting Conditions, Caps, and Drops The PPACA made it illegal for insurance companies to deny coverage to anyone on the basis of a preexisting medical condition. As just discussed, this ban led to the enrollment of millions of individuals with costly health conditions.

The PPACA also increased the amount of money that insurance companies had to pay out by prohibiting them from imposing annual or lifetime expenditure caps.

To prevent insurance companies from dropping policyholders just because they developed a costly illness, the PPACA also made fraud the only legal reason that an insurance company could drop a policyholder. Because this provision forced insurance companies to keep very sick people enrolled, it also entailed significant cost increases for insurance companies.

Employer Mandate The PPACA has an **employer mandate** (requirement) that every firm with 50 or more full-time employees must either purchase health insurance for each of their full-time employees or pay a fine of \$2,000 per employee. This provision of the law is intended to extend employer-paid health insurance to as many workers as possible so that private employers, rather than the government, will bear as much of the cost of extending insurance coverage to the uninsured as possible.

Firms with fewer than 50 full-time employees are exempt from the employer mandate because the high cost of health insurance might bankrupt many smaller firms.

Personal Mandate The PPACA contains a **personal mandate** (requirement) that individuals must purchase health insurance for themselves and their dependents unless they are already covered by either government insurance or employer-provided insurance. Anyone refusing will be fined. The fine is the larger of either \$695 per uninsured family member or 2.5 percent of family income.

As we will explain next, the PPACA contains extensive subsidies to ensure that poorer people will not be financially devastated by the personal mandate’s requirement to buy health insurance. However, it must be understood that the point of the personal mandate is to force higher-income healthy people (especially healthy young workers) to buy health insurance so that their insurance premiums can help pay for the high health care bills of those with costly medical conditions as well as the subsidies needed to make health insurance affordable for those with lower incomes.

Covering the Poor In the years before the PPACA was passed, millions of poorer Americans lacked private health insurance either (a) because they were unemployed and thus not receiving employer-provided health insurance or (b) because their employers did not provide health insurance. Some of these poorer Americans could obtain government health insurance through either Medicaid or Medicare, but those who did not found themselves without any sort of health insurance, either private or public.

The PPACA attempts to cover those with lower incomes in three ways. First, the employer mandate will induce many larger employers to provide insurance for all of their full-time employees, including the poorer ones. Second, the law expands the Medicaid system to cover anyone whose income is

less than 133 percent of the poverty level. Third, the PPACA subsidizes the purchase price of health insurance for those who must buy their own health insurance to comply with the individual mandate.

The subsidies actually extend well into the middle class because they extend upward along the income scale even to persons making up to four times the federal poverty level. Taking into account the fact that individuals and households have different federal poverty levels, the subsidies would extend to individuals making up to about \$44,000 per year and families of four making up to about \$88,000 per year. By comparison, full-time workers had median annual earnings of about \$41,560 in 2011, while the median family income in 2011 was about \$50,054. The subsidies extend into the upper half of the income distribution because health insurance is so expensive that the personal mandate would have been financially ruinous for even middle-income workers if it had not been accompanied by subsidies.

A complicated formula adjusts the size of the subsidies by income level. The formula kicks in at 133 percent of the federal poverty level because anyone earning less will receive free government health insurance through Medicaid. For those earning slightly more than 133 percent of the poverty level (about \$15,000 for an individual and about \$30,700 for a family of four), the subsidies would be large enough so that they would not have to spend more than about 4 percent of their incomes purchasing health insurance. The subsidies get progressively less generous as incomes rise, so that those earning three to four times the poverty level would be subsidized such that they would have to pay about 10 percent of their incomes to buy health insurance.

Insurance Exchanges Individuals shopping for their own insurance will do so in government-regulated markets called **insurance exchanges**. There will be one exchange for each state, and federal regulators will only allow policies meeting certain standards to be offered. The regulators cannot set prices directly but will have the authority to withdraw approval from any insurer that requests a price increase that regulators deem to be unjustified on the basis of higher costs. It is hoped that the exchanges will reduce the growth of health care spending by fostering competition among insurance companies.

Other Provisions The 2,400-page PPACA contains hundreds of additional provisions. Some of the more publicized include:

- Mandating that the adult children of parents with employer-provided health insurance remain covered by their parents' insurance through age 26.
- Making it illegal for insurance companies to charge copayments or apply deductibles to annual checkups or preventive care.

PPACA Implementation Problems

By early 2016, the PPACA had been in effect for over two years. Several problems were apparent, including:

- Many employers reacted to the very

expensive employer mandate to purchase health insurance for full-time employees by limiting workers to only part-time work. These employees thus ended up without insurance—and with lower earnings, to boot.

- 27 states had declined to set up their own insurance exchanges, thereby leaving the task up to the federal government.
- Among the 23 states that did set up exchanges, 12 of the exchanges had been shut down after going bankrupt and another 8 were in serious risk of going bankrupt over the next year.

State insurance exchanges fared badly because the PPACA required health insurance rates to be the same for all applicants in a given state. Unfortunately, older adults run up far more health care costs than younger people. So there is an implicit wealth transfer from younger people to older people when both are being charged the same rate for health insurance.

As you might imagine, many younger people declined to participate since on average they were going to be paying more in premiums than they were likely to receive in benefits. By contrast, older people were eager to join because they would on average receive more in benefits than they paid in premiums.

Those two tendencies collapsed the insurance exchanges because there weren't enough healthy young people overpaying for health insurance to compensate for the high health care costs run up by the older people who were underpaying.

- Requiring insurers to spend at least 80 percent of the money they receive in premiums on either health care or improving health care.

Taxes To help pay for the extension of health insurance to millions of previously uninsured people, the PPACA imposes several new taxes. The more prominent are:

- A 0.9 percentage point increase in the Medicare payroll tax for individuals earning more than \$200,000 per year and for married couples earning more than \$250,000 per year.

Singapore's Efficient and Effective Health Care System

How Does Singapore Deliver Some of the Best Health Care in the World while Spending 72 Percent Less per Person than the United States?

In every health quality category monitored by the World Health Organization, the small island nation of Singapore is either number one in the world or near the top of the list. Among other achievements, Singapore has the world's lowest rate of infant mortality and the world's fourth-highest life expectancy.

One might expect that achieving these exceptional outcomes would be extremely expensive. But Singapore is also number one in another category. It spends less per person on health care than any other developed nation. In 2015 the United States spent 17.5 percent of its GDP on health care. Singapore spent just 4.9 percent.

How does Singapore deliver world-class health care while spending less than any other developed nation? The answer is a unique combination of government mandates to encourage competition, high out-of-pocket costs for consumers, and laws requiring people to save for future health expenditures.

Competition is encouraged by forcing hospitals to post prices for each of their services. Armed with this information, patients can shop around for the best deal. The government also publishes the track record of each hospital on each service so that consumers can make informed decisions about quality as well as price. With consumers choosing on the basis of cost and quality, local hospitals compete to reduce costs and improve quality.

Singapore also insists upon high out-of-pocket costs to avoid the overconsumption and high prices that result when insurance policies pick up most of the price for medical procedures. Indeed, out-of-pocket spending represents about 92 percent of all nongovernment health care spending in Singapore, compared to just 11 percent in the United States.

Having to pay for most medical spending out of pocket, however, means that Singapore's citizens are faced with having to pay for most of their health care themselves. How can this be done without bankrupting the average citizen? The answer is mandatory health savings accounts.

Singapore's citizens are required to save about 6 percent of their incomes into "MediSave" accounts. MediSave deposits are private property, so people have an incentive to spend the money in their accounts wisely. In addition, the citizens of Singapore also know that they won't be left helpless if the money in their MediSave accounts runs out. The government subsidizes the health care of those who have

exhausted their MediSave accounts as well as the health care of the poor and others who have not been able to accumulate much money in their MediSave accounts.

Could elements of Singapore's system help to hold down medical costs in the United States? Two cases suggest that the answer is yes.

First, consider the health care plan offered by Whole Foods Markets to its employees. The company deposits \$1,800 per year into a "personal wellness account" for each of its full-time employees. It simultaneously pays for a high-deductible health insurance plan that will pick up 100 percent of all medical expenses exceeding \$2,500 in a given year. This combination implies that employees are *at most* on the hook for \$700 a year—that is, for the difference between the \$1,800 in their personal wellness accounts and the \$2,500 deductible on their health insurance policy (above which, all medical expenses are covered).

Because both the money in the personal wellness account as well as the \$700 that employees might have to spend before reaching the \$2,500 deductible are personal property, Whole Foods Markets has effectively created a system in which all medical spending up to \$2,500 is an out-of-pocket expense. This forces employees to examine the opportunity cost of any potential medical expenditure. The result is less spending.

A similar plan offered to employees of the State of Indiana puts \$2,750 per year into a health savings account and then provides an insurance policy that covers 80 percent of any medical expenses between \$2,750 and \$8,000 and 100 percent of any expenses above \$8,000. The Indiana plan's design means that any state employee volunteering for the plan must pay 100 percent of all spending up to \$2,750 from their health savings accounts. As with Singapore's system and Whole Foods' system, this encourages prudence. The result has been a 35 percent decline in total health care spending for those

who volunteered for the plan versus state employees who opted to stick with the state's traditional PPO option. In addition, an independent audit showed that participants in the new plan were not cutting corners by skimping on preventive care like annual mammogram screenings for cancer. Thus, the savings appear to be permanent and sustainable.

The program is also popular, with positive personal recommendations causing voluntary participation to rise from 2 percent of state employees in the program's first year to 70 percent of state employees in the program's second year.

- A 3.8 percentage point increase in the capital gains tax for individuals earning more than \$200,000 per year and for married couples earning more than \$250,000 per year.
- A 40 percent tax payable by employers on any employer-provided insurance policy whose premium exceeds \$10,200 per year for individual coverage or \$27,500 per year for family coverage.
- A 2.9 percent excise tax applied to everything sold by medical device manufacturers.
- A 10 percent tax levied on indoor tanning.

Objections and Alternatives

The PPACA was strongly opposed and passed Congress without a single approving vote in either chamber of Congress from members of the minority (Republican) party. The legislation also failed to achieve majority support in public opinion polls conducted on the eve of the legislation's passage.

Some of those voicing objections worried that federal control over the pricing and content of insurance policies would lead to greater inefficiencies in health care by adding additional layers of bureaucracy. Others objected because they felt that the PPACA might be the first step toward the creation of a national health insurance system in which non-price rationing might become necessary to hold down expenditures. Yet others pointed to financial projections indicating that the revenue sources legislated by the PPACA would not be nearly sufficient to cover future health care expenses, especially over the longer run.

An additional concern was whether the PPACA would reduce the growth rate of health care expenditures and thereby fulfill the president's promise that the law would "bend the cost curve down." Many economists worried that the large subsidies provided by the law would raise prices and increase consumption (as in Figure 24.3 and the nearby discussion). With even middle-class individuals and families eligible for significant government subsidies, inefficient health care spending might increase significantly.

As an alternative, some opponents of the PPACA pointed to the health care system in Singapore and recent experiments

with the health insurance offered to employees of the State of Indiana. Both systems reduce wasteful expenditures by increasing the percentage of health care spending that comes directly out of consumers' pockets, thereby forcing them to consider opportunity costs and weigh marginal benefits against marginal costs. (See this chapter's Last Word for more.)

In evaluating the pros and cons of the PPACA, one thing seems clear. It will not be the last word on health care reform in America. Indeed, the economic challenges related to health care will only get stronger. The combination of an aging population and advances in medical technology seem to be on a collision course with the reality of economic scarcity such that individuals and society will face increasingly difficult choices about how much health care to consume and how to pay for it.

QUICK REVIEW 24.4

- ✓ The Patient Protection and Affordable Care Act (PPACA) is an attempt to extend either private or public insurance coverage to all U.S. citizens and legal residents.
- ✓ The PPACA includes (1) a *personal mandate* that requires all citizens and legal residents to purchase insurance coverage for themselves and their dependents if they are not already provided with insurance by their employer or by the government as well as (2) an *employer mandate* that requires all firms with more than 50 full-time employees to either offer health insurance coverage to their full-time employees or pay large fines.
- ✓ The PPACA also bans insurance companies from denying coverage on the basis of preexisting conditions; includes various subsidies so that the personal mandate will not bankrupt the poor and middle class; provides for the creation of state insurance exchanges, where individuals can comparison shop for government-approved health insurance policies; and imposes various taxes to help pay for the increased expenditures that will be required to extend insurance coverage to the previously uninsured.

SUMMARY

L024.1 Convey important facts about rising health care costs in the United States.

The U.S. health care industry comprises 19 million workers (including about 708,300 practicing physicians) and 5,600 hospitals.

Unlike nations with publicly funded systems of national health insurance, the United States delivers a large fraction of its health care through private, employer-provided health insurance.

U.S. health care spending has increased both absolutely and as a percentage of GDP.

L024.2 Relate the economic implications of rising health care costs.

Rising health care costs and prices have (a) reduced access to the health care system, (b) contributed to slower real wage growth and

expanded the employment of part-time and temporary workers, and (c) caused governments to restrict spending on nonhealth programs and to raise taxes.

The core of the health care problem is an alleged overallocation of resources to the health care industry.

L024.3 Discuss the problem of limited access to health care for those without insurance.

About 30 million Americans, or 9 percent of the population, did not have health insurance in 2015. The uninsured were concentrated among the poor, the chronically ill, the unemployed, the young, those employed by small firms, and low-wage workers.

L024.4 List the demand and supply factors explaining rising health care costs.

Special characteristics of the health care market include (a) the belief that health care is a “right,” (b) an imbalance of information between consumers and suppliers, (c) the presence of positive externalities, and (d) the payment of most health care expenses by private or public insurance.

While rising incomes, an aging population, and substance abuse have all contributed to an increasing demand for health care, the role of doctors is also significant. Because of asymmetric information, physicians influence the demand for their own services. The fee-for-service payment system, combined with defensive medicine to protect against malpractice suits, also increases the demand for health care.

The moral hazard problem arising from health insurance takes two forms: (a) people may be less careful of their health and (b) there is an incentive to overconsume health care.

The exemption of employer-paid health insurance from the federal income tax subsidizes health care. The subsidy increases demand, leading to higher prices and a likely overallocation of resources to health care.

Countries with systems of national health insurance also increase demand by subsidizing health care. Facing limited budgets, those countries engage in nonprice rationing to restrict health care expenditures. Rationing mechanisms include waiting lists, committees that set standards for denial of service, and restrictions on capital spending.

Because private insurance does not involve government expenditures, the state regulators charged with regulating private insurance companies in the United States focus more on expanding politically popular benefits than on restricting costs.

Slow productivity growth in the health care industry and, more important, cost-increasing advances in health care technology have restricted the expansion of the supply of medical care and have boosted prices.

L024.5 Describe the cost-containment strategies that rely on altering the financial incentives facing either patients or health service providers.

Strategies that have attempted to contain health care prices and spending include (a) insurance deductibles and copayments to confront consumers with opportunity costs, (b) managed-care organizations—preferred provider organizations (PPOs) and health maintenance organizations (HMOs)—that attempt to restrict their members’ use of health services, (c) the diagnosis-related-group (DRG) system that caps the amount Medicare will spend on any procedure, and (d) health savings accounts (HSAs) that also confront individuals with opportunity costs when they spend out of their tax-free HSA accounts.

L024.6 Summarize the goals of the Patient Protection and Affordable Care Act and the major changes that it institutes.

The Patient Protection and Affordable Care Act (PPACA) of 2010 is an attempt to extend either private or public (Medicare and Medicaid) insurance coverage to all U.S. citizens and legal residents.

Enrolling millions of previously uninsured people (including the chronically ill) into health insurance will be costly, so the PPACA includes a personal mandate that requires all citizens and legal residents to purchase insurance coverage for themselves and their dependents if they are not already provided with insurance by their employer or by the government. The goal is to compel healthy people to purchase insurance so that their premiums can help to pay for the health care costs of the previously uninsured (many of whom are likely to be chronically ill.)

The PPACA also (a) bans insurance companies from denying coverage on the basis of preexisting conditions, (b) includes various subsidies so that the personal mandate will not bankrupt the poor and middle class, (c) provides for the creation of state insurance exchanges where individuals can comparison shop for government-approved health insurance policies, and (d) imposes various taxes to help pay for the increased expenditures that will be required to extend insurance coverage to the previously uninsured.

REVIEW QUESTIONS

- Which of the following best describes the United States’ level of health care spending as compared to that of other nations? **L024.1**
 - The lowest of all nations.
 - A bit lower than average.
 - Average.
 - A bit higher than average.
 - The highest of all nations.
- Which of the following make a person *less* likely to have health insurance? (Select one or more answers from the choices shown.) **L024.3**
 - Working for a larger firm.
 - Being a low-wage worker.
 - Being employed.
 - Having excellent health.
 - Being chronically ill.
- A patient named Jen visits Dr. Jan. Dr. Jan is nearly certain that Jen only has a cold. But because Dr. Jan is afraid of malpractice lawsuits, she orders an extensive battery of tests just to make sure that Jen can never claim—if she turns out to have something more severe—that Dr. Jan shirked her duties as a medical professional. Dr. Jan’s behavior is an example of: **L024.4**
 - Asymmetric information.
 - Fee-for-service.
 - Defensive medicine.
 - Positive externalities.
- All MegaCorp employees who stay on the job for more than three years are rewarded with a 10 percent pay increase and coverage under a private health insurance plan that MegaCorp pays for. Tina just passed three years as a MegaCorp employee and reacts to having health insurance by taking up several dangerous sports because now she knows that the insurance plan will pay for any injuries that she may sustain. This change in Tina’s behavior is known as: **L024.4**
 - Defensive medicine.
 - Asymmetric information.
 - The moral hazard problem.
 - The personal mandate.

5. By increasing demand, health insurance creates: **LO24.4**
 - a. A deadweight loss related to overconsumption.
 - b. A deadweight loss related to underconsumption.
 - c. Neither of the above.
6. Ralph will consume any health care service just as long as its MB exceeds the money he must pay out of pocket. His insurance policy has a zero deductible and a 10 percent copay, so Ralph only has to pay 10 percent of the price charged for any medical procedure. Which of the following procedures will Ralph choose to consume? **LO24.5**
 - a. An \$800 eye exam that has an MB of \$100 to Ralph.
 - b. A \$90 hearing test that has an MB of \$5 to Ralph.
 - c. A \$35,000 knee surgery that has an MB of \$3,000 to Ralph.
 - d. A \$10,000 baldness treatment that has an MB of \$16,000 to Ralph.
7. True or False. Under the PPACA, Americans are free to decide for themselves whether or not they should have health insurance coverage. **LO24.6**

PROBLEMS

1. Suppose that the price elasticity for hip replacement surgeries is 0.2. Further suppose that hip replacement surgeries are originally not covered by health insurance and that at a price of \$50,000 each, 10,000 such surgeries are demanded each year. **LO24.2**
 - a. Suppose that health insurance begins to cover hip replacement surgeries and that everyone interested in getting a hip replacement has health insurance. If insurance covers 50 percent of the cost of the surgery, by what percentage would you expect the quantity demanded of hip replacements to increase? What if insurance covered 90 percent of the price? (Hint: Do not bother to calculate the percentage changes using the midpoint formula given in Chapter 6. If insurance covers 50 percent of the bill, just assume that the price paid by consumers falls 50 percent.)
 - b. Suppose that with insurance companies covering 90 percent of the price, the increase in demand leads to a jump in the price per hip surgery from \$50,000 to \$100,000. How much will each insured patient now pay for a hip replacement surgery? Compared to the original situation, where hip replacements cost \$50,000 each but people had no insurance to help subsidize the cost, will the quantity demanded increase or decrease? By how much?
2. The federal tax code allows businesses but not individuals to deduct the cost of health insurance premiums from their taxable income. Consider a company named HeadBook that could either spend \$5,000 on an insurance policy for an employee named Vanessa or increase her annual salary by \$5,000 instead. **LO24.4**
 - a. As far as the tax code is concerned, HeadBook will increase its expenses by \$5,000 in either case. If it pays for the policy, it incurs a \$5,000 health care expense. If it raises Vanessa's salary by \$5,000, it incurs \$5,000 of salary expense. If HeadBook is profitable and pays corporate profit taxes at a marginal 35 percent rate, by how much will HeadBook's tax liability be reduced in either case?
 - b. Suppose that Vanessa pays personal income tax at a marginal 20 percent rate. If HeadBook increases her salary by \$5,000, how much of that increase will she have after paying taxes on that raise? If Vanessa can only devote what remains after paying taxes on the \$5,000 to purchasing health insurance, how much will she be able to spend on health insurance for herself?
 - c. If HeadBook spends the \$5,000 on a health insurance policy for Vanessa instead of giving it to her as a raise, how many more dollars will HeadBook be able to spend on Vanessa's health insurance than if she had to purchase it herself after being given a \$5,000 raise and paying taxes on that raise?
 - d. Would Vanessa prefer to have the raise or to have HeadBook purchase insurance for her? Would HeadBook have any profit motive for denying Vanessa her preference?
 - e. Suppose the government changes the tax law so that individuals can now deduct the cost of health insurance from their personal incomes. If Vanessa gets the \$5,000 raise and then spends all of it on health insurance, how much will her tax liability change? How much will she be able to spend on health insurance? Will she now have a preference for HeadBook to buy insurance on her behalf?
3. Preventive care is not always cost-effective. Suppose that it costs \$100 per person to administer a screening exam for a particular disease. Also suppose that if the screening exam finds the disease, the early detection given by the exam will avert \$1,000 of costly future treatment. **LO24.4**
 - a. Imagine giving the screening test to 100 people. How much will it cost to give those 100 tests? Imagine a case in which 15 percent of those receiving the screening exam test positive. How much in future costly treatments will be averted? How much is saved by setting up a screening system?
 - b. Imagine that everything is the same as in part *a* except that now only 5 percent of those receiving the screening exam test positive. In this case, how much in future costly treatments will be averted? How much is lost by setting up a screening system?

Immigration

Learning Objectives

- L025.1** Describe the extent of legal and illegal immigration into the United States.
- L025.2** Discuss why economists view economic immigration as a personal human capital investment.
- L025.3** Explain how immigration affects average wages, resource allocation, domestic output, and group income shares.
- L025.4** Relate how illegal immigration affects employment and wages in low-wage labor markets and impacts state and local budgets.
- L025.5** Demonstrate how economics can inform current immigration discussions and attempts to reform immigration laws.

The population of the United States is composed largely of immigrants and their descendants, yet immigration has long been a matter of heated controversy. Some immigration issues are political, social, and legal; others are economic. Our focus will be on economic issues and **economic**

immigrants—international migrants motivated by economic gain. How many such immigrants come to the United States each year? What is their motivation and what economic impact do they make? Should more or fewer people be allowed to enter legally? What criteria, if any, should be used in allowing legal entry? How should the United States handle illegal immigration?¹

Number of Immigrants

L025.1 Describe the extent of legal and illegal immigration into the United States.

U.S. immigration consists of **legal immigrants**—immigrants who have permission to reside and work in the United States—and **illegal immigrants**—immigrants who arrive illegally or who enter legally on temporary visas but then fail to leave as stipulated. Legal immigrants include *permanent legal residents* (“green card” recipients) who have the right to stay in the country indefinitely and *temporary legal immigrants*, who have visas that allow them to stay until a specific date. Illegal immigrants are alternatively called unauthorized immigrants, illegal aliens, or, if working, undocumented workers.

¹Some of our discussion is drawn from our more advanced treatment of mobility and migration in our textbook on labor economics: Campbell R. McConnell, Stanley L. Brue, and David A. Macpherson, *Contemporary Labor Economics*, 10th ed. (New York: McGraw-Hill, 2013), pp. 263–290.

FIGURE 25.1 Legal immigration to the United States, 1980–2013. Legal immigration grew slowly between 1980 and 1988 and then spiked from 1989 to 1991 when previous illegal immigrants gained legal status as permanent residents under the terms of an amnesty program. Since that spike, legal immigration has remained relatively high, partly because the annual legal immigration quota was raised from 500,000 to 700,000. Within the totals are thousands of refugees, grantees of political asylum, and entrants under special provisions of the immigration law.

Legal Immigrants

Figure 25.1 shows the annual levels of legal immigration into the United States since 1980. The spike in legal immigration from 1989 to 1991 resulted from an amnesty program through which many formerly illegal immigrants became legal residents. Between 2004 and 2013, legal immigration averaged 1 million persons per year. This number is higher than for earlier decades because beginning in 1990 the federal government increased the annual immigration quota from 500,000 to 700,000.

Augmenting quota immigrants in some years are thousands of legal immigrants who are refugees (people who flee their country for safety) or are entrants to the United States under special provisions of the immigration law. As an example of the latter, the current **H1-B provision** of the immigration law allows 65,000 high-skilled workers in “specialty occupations” to enter and work continuously in the United States for six years. Such high-skilled occupations include high-tech workers, scientists, and professors.

A total of 990,553 people became permanent legal residents of the United States in 2013. About 55 percent of them were women and 45 percent were men. Around 58 percent of all legal immigrants were married.

As shown in Figure 25.2, about 66 percent of the 990,553 legal immigrants in 2013 were family-sponsored. They were parents, children, siblings, or other qualified relatives of legal permanent U.S. residents. Another 16 percent were admitted based on employment-based preferences. Most of these immigrants were sponsored by employers. Refugees, “diversity immigrants,” and others accounted for the remaining 18 percent. The 50,000 quota for diversity immigrants is filled with qualified immigrants who are from countries with low rates

of immigration to the United States. Because applications by diversity immigrants exceed the 50,000 quota, the slots are filled through an annual lottery.

Although the percentage varies somewhat each year, current U.S. immigration law is heavily weighted toward family reunification. This weighting is much heavier than that in Canada, which gives considerably stronger preference to immigrants with high levels of education and work skill. Of course, immigration by family ties and immigration by employment preferences are not necessarily mutually exclusive since a portion of the immigrants admitted through family ties are highly educated and skilled.

Table 25.1 shows the 10 leading countries of origin of U.S. legal permanent immigrants in 2013. Mexico topped the list with 135,028 immigrants, accounting for 14 percent of the total. China, the Philippines, and India were also heavy contributors to U.S. immigration in 2013. In recent years immigration has composed about one-third of the total growth of the U.S. population and one-half the growth of the U.S. labor force.

Illegal Immigrants

Our figures and tables do not include illegal immigrants. The U.S. Census Bureau estimates the number of illegal immigrants living in the United States through a residual approach. It finds the current total number of *all* immigrants through census surveys and then subtracts the sum of the past annual inflows of *legal* immigrants. The residuals are large. In fact, the net annual inflow of illegal immigrants averaged about 250,000 per year from 2000 to 2009, with over 60 percent arriving from Mexico and Central America. As this chapter's Last Word describes, however, the net annual inflow reversed during the 2007–2008 recession and then remained near zero through 2014.

While some illegal immigrants do move back and forth across the U.S.–Mexican border, in 2014 about 11.3 million illegal immigrants were residing continuously in the United States. Increasingly, illegal immigrants are continuous residents, not temporary workers who follow the agricultural harvest (as was typical several decades ago). An estimated 49 percent of the 11.3 million illegal immigrants originally came from Mexico, with many others arriving from nations spanning the globe. Illegal Mexican immigrants who work continuously in the United States work mainly outside of agriculture and, on average, have higher educational levels than Mexicans who do not migrate to the United States.

The Decision to Migrate

L025.2 Discuss why economists view economic immigration as a personal human capital investment.

People immigrate into the United States (emigrate from their home countries) legally or illegally:

- To take advantage of superior economic opportunities.
- To escape political or religious oppression in their home countries.
- To reunite with family members or other loved ones, usually prior immigrants, who are already in the United States.

As previously stated, our interest is in economic immigration. Why do some workers uproot their lives to move from some other country to the United States? Why do other workers stay put?

Earnings Opportunities

The main driver of economic immigration is the opportunity to improve the immigrant's earnings and therefore standard of living. The chief attractor for economic immigrants is the availability of higher pay in the United States. In particular, immigrants can earn much higher wages in the United States than doing identical or nearly identical jobs in their home countries. Stated in terms of economic theory, immigrants reap larger financial rewards from their respective stocks of human capital when working in the United States rather than in their home countries.

Recall that **human capital** is the stock of knowledge, know-how, and skills that enables a person to be productive, and thus to earn income. Other things equal, greater stocks of human capital (for example, more education or better training) result in greater personal productivity and earnings. But whatever someone's stock of education and skill, the value of that human capital depends critically on the capacity for it to earn income. That is where economic migration comes in. By securing higher earnings, migrants can increase—often quickly and dramatically—the value of their human capital. Economic migrants move from one country to another for the same reason many internal migrants move from one city or state to another within their home country: to increase their pay and therefore achieve a higher standard of living.

Other things equal, larger wage differences between nations strengthen the incentive to migrate and therefore increase the flow of immigrants toward the country providing the greater wage opportunities. Today, major “magnet countries” that attract a lot of immigrants include Australia, Switzerland, the United States, and several Western European nations. Global Perspective 25.1 shows the percentage of labor forces composed of foreign-born workers in selected nations in 2013, the latest year for which data are available. Along with earnings

opportunities, significant differences in educational opportunities, health care availability, and public pensions and welfare benefits play a role in international migration decisions.

Moving Costs

Immigration can be viewed as an investment decision. As with other investments, current sacrifices are necessary to achieve future benefits. In moving from one nation to another, workers incur personal costs. Some of these costs are explicit, out-of-pocket costs such as paying application fees (for example, \$1,010 for a green card) and a number of moving expenses. For illegal immigrants, a major explicit cost may be a payment to an expediter—a “coyote”—who charges as much as \$2,000 to smuggle someone into the United States and transport him or her to a major city such as Chicago, New York, Houston, or Los Angeles. Other costs of migrating are implicit. They are opportunity costs such as the income given up while the worker is moving and looking for a job in the new country. Still more subtle costs are incurred in leaving family and friends and adapting to a new culture, language, and climate. For illegal immigrants, there is the additional potential cost of being caught, jailed, and deported.

The prospective immigrant estimates and weighs all such costs against the expected benefits of the higher earnings in the new country. A person who estimates that the stream of future earnings exceeds the explicit and implicit costs of moving will migrate; a person who sees those costs as exceeding the future stream of earnings will stay put.²

Factors Affecting Costs and Benefits

Earnings differences provide the major incentive to migrate, but many nonwage factors also affect the cost-benefit evaluation of moving to another nation. Let’s look at two key factors.

Distance Other things equal, greater distance reduces the likelihood of migration. Most obvious, transportation costs rise with distance. In addition, migration to more distant countries is often seen as riskier because information about job market conditions in distant countries is usually less certain than about job market conditions in nearby countries (although the Internet has greatly reduced this difference in recent years). Finally, the farther the move, the greater the possible costs of maintaining contact with friends and family. In terms of expense, a short trip back across a border by automobile is one thing; an airline flight to a different continent, quite another.

The majority of international migrants move to countries relatively close to their home countries. Most Mexican

²As with other investment decisions, the decision to move internationally requires a comparison of the present value of the stream of additional earnings and the present value of the costs of moving. Present value considerations (discussed in Chapters 18 and 19) complicate the decision to migrate but do not alter the basic analytical framework.

GLOBAL PERSPECTIVE 25.1

Immigrants as a Percent of the Labor Force, Selected Advanced Industrial Countries

Immigrants make up relatively large percentages of the labor forces in several advanced industrial countries, including Australia, Austria, and the United States, but not in other countries such as Finland.

Source: Organization for Economic Cooperation and Development, www.oecd.org.

migrants move to the United States. The majority of Eastern European migrants move to Western Europe. Close proximity reduces the cost of the move relative to anticipated benefits.

Some migrants, of course, *do* move to far-away lands. They often reduce their costs of these long moves by following **beaten paths**—routes taken previously by family, relatives, and friends. They also tend to cluster, at least for awhile, in cities and neighborhoods populated by former and current immigrants. For example, thousands of Russian immigrants have located in Brooklyn, New York. Numerous Asian immigrants have located in San Francisco.

The earlier immigrants ease the transition for those who follow by providing job information, employment contacts, temporary living quarters, language help, and cultural continuity. That reduces the costs and increases the benefits of migration to those who follow. Eventually, some new immigrants exploit even better economic opportunities by moving from the original place of migration to other cities within the country to which they have migrated. New clusters of immigrants emerge and new migration networks result. For instance, these new clusters and networks help explain the rapid northward expansion of Latino immigrants during the past decade.

Age Younger workers are much more likely to migrate than older workers. Age affects both benefits and costs in the calculation to move or stay put. Particularly relevant, younger

migrants have more years to recoup their costs of moving. Spread over decades, the higher wage in the new country builds to a large accumulation of additional earnings relative to the earnings that would have accrued if the person had not moved. In contrast, older people are closer to retirement and therefore may conclude that moving abroad simply is not worth the effort. Their added earnings over their remaining work years simply will not be sufficient to cover the costs of the disruption and move.

Younger migrants also tend to have lower moving costs than older workers. For example, they often have accumulated fewer personal possessions to transport. Younger workers generally have fewer roots and ties to the local community and so may find it easier to adapt to new customs and cultures. This greater flexibility reduces the perceived costs of moving and increases the likelihood that the younger person will move.

Younger workers are also more likely to be single or, if married, less likely to have started families than older workers. The potential costs of migrating multiply rapidly when spouses and families are present. Finding affordable housing large enough for families and enrolling children in new schools complicate the potential move. Also, when both spouses work, the secondary wage earner may face a period of unemployment before finding a new job in the new country.

Other Factors Several other factors may affect the cost and benefit calculations of immigrants into the United States. Studies show that immigrants who lack English language skills do not, in general, fare as well in the U.S. workforce as immigrants who have those skills when they arrive. For some highly skilled immigrants, lower tax rates or opportunities to set up businesses in the United States may be the draw. Also, some immigrants to the United States may be willing to endure low or even negative personal returns on immigration simply so that their children have greater economic opportunities than at home.

QUICK REVIEW 25.1

- ✓ An average of 1 million legal immigrants entered the United States each year between 2004 and 2013.
- ✓ In 2013 Mexico was the greatest single contributor (14 percent) to U.S. legal immigration. Hundreds of thousands of additional legal immigrants arrived from China, the Philippines, India, and many other nations.
- ✓ Economists view economic migration as a personal investment; a worker will move internationally when the expected gain in earnings exceeds the explicit and implicit costs of moving.
- ✓ Other things equal, the greater the migration distance and the older the prospective migrant, the less likely the person will move.

Economic Effects of Immigration

L025.3 Explain how immigration affects average wages, resource allocation, domestic output, and group income shares. Immigration creates personal gains for movers, and also affects wage rates, efficiency, output, and the division of income. Like international trade, migration produces large economic benefits but also creates short-term winners and losers. In particular, we will see that the wage-rate and division-of-income aspects of immigration are two main sources of controversy.

Personal Gains

The fact that economic immigration to the United States is sizable and continuous affirms that in general the economic benefits of immigration to the immigrants exceed their costs. In economic terms, the inflows of legal and illegal immigration indicate that this investment has a positive return to movers. Studies confirm that the returns to immigrating to the United States are, on average, quite substantial. This should not be a surprise. For example, the real wages earned by recent Mexican male migrants to the United States are as much as six times higher than those earned by similarly educated men in Mexico.

Nevertheless, not all economic immigrants to the United States succeed. Migration decisions are based on expected benefits and are made under circumstances of uncertainty and imperfect information. High average rates of return do not guarantee that all migrants will benefit. In some cases the expected gain from immigration does not materialize—the anticipated job is not found in the new country, the living costs are higher than anticipated, the anticipated raises and promotions are not forthcoming, the costs of being away from family and friends are greater than expected. Major **backflows**—return migration to the home country—therefore occur in most international migration patterns, including those between the United States and other countries.

Although this return migration may be costly to those involved, it increases the availability of information about the United States to other potential migrants. These people are then able to better assess the benefits and costs of their own potential moves.

Also, although economic immigrants on average improve their standard of living, they may or may not achieve pay parity with similarly educated native-born workers. The skills that migrants possess are not always perfectly transferable between employers in different countries because of occupational licensing requirements, specific training, or differing languages. This lack of **skill transferability** may mean that migrants, although improving their own wage, may earn less than similarly employed native-born workers in the United States. Studies find that this is particularly true for immigrants who lack English-language skills.

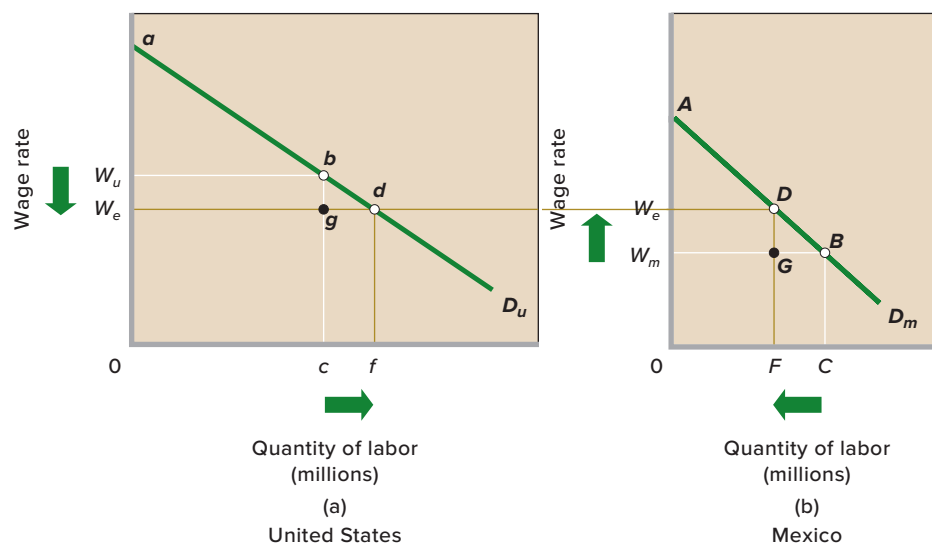

FIGURE 25.3 A simple immigration model. (a) The migration of low-wage Mexican labor by the amount cf to the United States increases U.S. domestic output by $cbdf$, reduces the U.S. wage rate from W_u to W_e , and increases U.S. business income by W_eW_ubd . (b) The out-migration of labor of CF from Mexico reduces Mexican domestic output by $FDBC$, raises the wage rate from W_m to W_e , and lowers Mexican business income by W_mW_eDB . Because the U.S. gain in domestic output of $cbdf$ exceeds Mexico's loss of domestic output of $FDBC$, the migration depicted increases economic efficiency and produces a net gain of world output.

On the other hand, a great deal of economic migration is characterized by **self-selection**. Because migrants choose to move while others with similar skills do not, it is possible that those who move possess greater motivation for personal economic gain and greater willingness to sacrifice current consumption for higher levels of later consumption. If so, these migrants may overcome the problem of imperfect skill transferability and eventually outdo domestic-born workers in wage and salary advancement. This possibility is particularly true of highly skilled immigrants such as scientists, engineers, physicians, and entrepreneurs.

Many U.S. firms have been founded by immigrants or their children. Their impact has been large, with fully 40 percent of the businesses listed in the Fortune 500 ranking of the largest U.S. companies having been founded by immigrants or their offspring. These companies employed over 10 million people worldwide in 2010 and had combined annual revenues of \$4.2 trillion dollars, a figure larger than the respective gross domestic products (GDPs) of all but three countries, the United States, China, and Japan. Famous American companies founded by immigrants or their children include Apple, AT&T, Budweiser, eBay, General Electric, Google, IBM, and McDonald's.

Impacts on Wage Rates, Efficiency, and Output

Although the personal outcomes of immigration are relatively straightforward and easy to understand, the broader economic outcomes are somewhat complicated and obscure. A simple economic model of migration will help us sort through key cause-effect relationships and identify broader economic outcomes. In Figure 25.3a, D_u is the demand for labor in the United States; in Figure 25.3b, D_m is the demand for labor in Mexico. The demand for labor presumably is greater in the

United States because it has more capital, advanced technology, and better infrastructure that enhance the productivity of labor. (Recall from Chapter 16 that the strength of labor demand is based on the marginal revenue productivity of labor.) Conversely, labor demand in Mexico is weaker since machinery and equipment are less abundant relative to labor, technology is less advanced, and infrastructure is less developed. We also assume that the before-migration labor forces of the United States and Mexico are c and C , respectively; that neither country is experiencing substantial long-term unemployment; and that labor quality in the two countries is the same.

If we further suppose that migration (1) has no cost, (2) occurs solely in response to wage differentials, and (3) is unimpeded by law in both countries, then workers will migrate from Mexico to the United States until wage rates in the two countries are equal at W_e . At that level, $C - F$ (equals $f - c$) workers will have migrated from Mexico to the United States. Although the U.S. wage level will fall from W_u to W_e , domestic output (the sum of the marginal revenue products of the entire workforce) will increase from $0abc$ to $0adf$. This domestic output is the total output produced within the borders of the United States and equals U.S. domestic income.

In Mexico, the wage rate will rise from W_m to W_e , but domestic output will decline from $0ABC$ to $0ADF$. Observe that the gain in domestic output $cbdf$ in the United States exceeds the loss of domestic output $FDBC$ in Mexico. The migration from Mexico to the United States has clearly increased the world's output and income.

The elimination of barriers to the international flow of labor tends to create worldwide **efficiency gains from migration**. The same number of workers—rearranged among countries—produces greater total output and income after migration than before migration. The world gains output (and income) because the freedom to migrate enables people to move to countries where they can contribute more to world

Skilled migrants, whether permanent or temporary, enrich our scientific and academic communities, boost the technical capabilities of U.S. firms (and the native-born workers employed there), augment the supply of health care providers, and pay more in taxes than they absorb in government services. Many of these workers were educated in American universities and nearly all adjust easily to life in the United States in terms of language skills and employment. They make major innovative contributions in science, medicine, and engineering, and help keep the United States at the forefront of technological capability.*

Since 1990, U.S. immigrants have founded 1 of every 4 public companies backed by venture capital. Yahoo!, Intel, eBay, Google, and Sun Microsystems all have one or more immigrant founders. About half the engineers and people with computer science doctorates in the United States are foreign-born. One-fourth of U.S. major league baseball players were born abroad. Children of immigrants often dominate U.S. math and science competitions. And our list could go on.[†]

production. Economic migration not only provides a positive investment return to the mover, it produces an overall efficiency gain. Migration enables the world to produce a larger output with its currently available resources. So labor mobility joins capital mobility and international trade in enhancing the world's standard of living.

Income Shares

With personal gains and overall productivity gains, why would anyone oppose immigration? Our graphical model helps answer that question. There are specific groups of gainers and losers from immigration in both nations.

In Figure 25.3, as workers move from Mexico to the United States in search of higher wages, U.S. output will increase while Mexican output will decrease. These gains partly explain why the United States encourages a relatively high level of immigration through high annual quotas. It also explains why

some countries try to discourage outflows of labor from their countries. In particular, countries are rightfully concerned about the emigration of highly educated workers, particularly when those citizens received subsidized education at home. Such undesirable outflows are commonly called **brain drains**.

Figure 25.3 reveals a second consequence of immigration on income shares. The decline in the wage rate from W_u to W_e in the United States reduces the wage income of native-born U.S. workers from $0W_u bc$ to $0W_e gc$. The opposite outcome occurs in Mexico, where the average wage for the native-born workers who do not migrate rises.

Although we can specify income gains and losses to domestic-born workers, we cannot say what will happen to the total wage income (= domestic-born wage income + immigrant wage income) in each country. That depends on the elasticities of labor demand. For example, if labor demand is elastic, the wage decrease in the United States will increase total wage income. In contrast, if labor demand is inelastic, the same wage decrease will cause total wage income to fall.

The immigration-caused decline in wage income for native-born U.S. workers is a major reason that many U.S. labor unions oppose increasing immigration quotas in the United States. Unions tend to resist policies that reduce the wages of their current membership or undercut their bargaining power by creating larger pools of potential workers for nonunion firms. In direct contrast, the increase in wages in the outflow country is a possible reason why labor groups in Mexico show little concern about the large-scale outflow of Mexican labor to the United States.

Finally, Figure 25.3 shows that the immigration enhances business income in the United States while reducing it in Mexico. The before-immigration domestic output and income in the United States is represented by area $0abc$. Total wage income is $0W_u bc$ —the wage rate multiplied by the number of workers. The remaining triangular area $W_u ab$ shows business income before immigration. The same reasoning applies to Mexico, where the triangle $W_m AB$ represents before-immigration business income.

Unimpeded immigration increases business income from $W_u ab$ to $W_e ad$ in the United States and reduces it from $W_m AB$ to $W_e AD$ in Mexico. Other things equal, owners of U.S. businesses benefit from immigration; owners of Mexican businesses are hurt by emigration. These outcomes are what we would expect intuitively; the United States is gaining “cheap” labor and Mexico is losing “cheap” labor. This conclusion is consistent with the historical fact that U.S. employers have often actively recruited immigrants and have generally supported higher immigration quotas, liberal guest-worker programs, and expanded specialized work visas such as H1-Bs.

Complications and Modifications

Our model is a purposeful simplification of the much more complex actual reality. Thus, it is not surprising that the

model includes simplifying assumptions and overlooks some factors that may be important in certain situations. Relaxing some of the assumptions and introducing the omitted factors may affect our conclusions.

Costs of Migration Our model assumed that the movement of workers from Mexico to the United States is without personal cost, but we know that migrants incur explicit, out-of-pocket costs of physically moving and the implicit opportunity costs of forgone income during the move and transition.

In Figure 25.3, the presence of migration costs means that the flow of labor from Mexico to the United States will stop short of that required to close the wage differential entirely. Wage rates will remain somewhat higher in the United States than in Mexico, and that wage-rate difference will not encourage further migration to close up the wage gap. At some point, the remaining earnings gap between the two countries will not be sufficient to cover the marginal cost of migration. Migration will end, and the total output and income gain from migration will be less because wages have not equalized.

Remittances and Backflows Although most of the workers who acquire skills in the country of immigration do not return home, some migrants see their moves as temporary. They move to a more highly developed country; accumulate some wealth, training, or education through hard work and frugality; and return home to establish their own enterprises. During their time in the new country, these and other migrants frequently make sizable **remittances** to their families at home. These money transfers to the home country redistribute the net gain from migration between the countries involved.

In Figure 25.3, remittances by Mexican workers in the United States to their relatives in Mexico would cause the gain in U.S. income retained in the United States to be less than the domestic output and income gain shown. Similarly, the loss of income available in Mexico would be less than the domestic output and income loss shown. The World Bank estimates that \$25 billion of remittances—an amount equal to 2 percent of Mexico’s GDP—flowed to Mexico from other countries in 2015. Most of these remittances originate in the United States and are a major reason Mexico favors liberal U.S. immigration laws and generally opposes U.S. policies to stem the flow of illegal immigrants across the U.S. border. (Global Perspective 25.2 shows selected developing countries receiving remittances by emigrants in 2015. For many developing countries, remittances exceed foreign direct investment—purchases by foreigners of lasting ownership interests in domestic firms—as a source of foreign currencies available to buy imported goods and services.)

Along with remittances, backflows of migrants to their home countries might also alter gains and losses through time. For example, if some Mexican workers who migrated to

the United States acquired substantial labor market or managerial skills and then returned home, their enhanced human capital might contribute substantially to economic development in Mexico. Further, some of the more successful U.S. immigrants eventually may use their expertise and wealth to help build new businesses in Mexico. Both will eventually increase labor demand in Mexico and raise wage rates there.

Complementary versus Substitute Resources

Although the average wage rate of domestic-born workers may decline because of immigration, not all such workers will see their wages fall. Many immigrant workers and domestic-born workers are **complementary resources** rather than **substitute resources** (Chapter 16). When that is the case, the lower wage rate resulting from large-scale immigration reduces production costs, creating an output effect that raises labor demand for certain domestic-born workers. For example, the large number of immigrants working in the home building industry lowers construction wages and reduces the cost of home building. That in turn increases the number of houses built and sold, which increases the demand for domestic-born residents who help manufacture sheet rock, plumbing products, air conditioners, major appliances, and other home products.

Expansion of Capital Long-run effects on capital are another reason native-born citizens may not be permanently harmed to the extent suggested by the simple immigration model. The stock of capital was implicitly constant in both countries in Figure 25.3, fixing the demand curves in place. But the rise in business income in the United States relative to the stock of capital produces a higher rate of return on capital. The higher rate of return stimulates overall investment, which in the long run adds to the size of the nation's stock of capital. Normally, the addition of new capital such as plant and equipment raises labor productivity, lowers production costs, and reduces product prices. As a result, wages and salaries rise because of increased demand for labor.

On the other hand, the inflow of illegal workers into certain low-wage occupations such as field harvesting may stifle R&D, technological advance, and investment in some industries. The easy availability of inexpensive legal or illegal immigrant labor provides little incentive to mechanize or otherwise economize on the use of labor. In this regard, economists note that the temporary slowing of the flow of illegal agricultural workers after the terrorist attacks of September 11, 2001, increased the purchase of mechanical harvesting equipment such as tree-trunk shakers used to harvest oranges.

Full Employment versus Unemployment Our model conveniently assumes full employment in both countries. Mexican workers presumably leave low-paying jobs to take higher-paying jobs in the United States (more or less immediately). However, in many circumstances, the factor that pushes immigrants from their homelands is not simply low wages but chronic unemployment or underemployment. Many developing countries have large populations and surplus labor. A sizable number of workers are either unemployed or so grossly underemployed that their contribution to domestic output is zero or near zero.

If we allow for this possibility, then Mexico would gain rather than lose by having such workers emigrate. Unemployed Mexicans are making no or little contribution to Mexico's domestic output and must be sustained by transfers from the rest of the labor force. The remaining Mexican labor force will be better off by the amount of the transfers after the unemployed workers have migrated to the United States.

The unemployed workers moving to the United States may reflect **negative self-selection**, in which movers are less capable and perhaps less motivated than similarly educated people who did not immigrate. This possibility could conceivably join higher domestic wages and large remittances as an explanation of why Mexico generally opposes stronger border enforcement by the United States.

Conversely, if the Mexican immigrant workers are unable to find jobs in the United States and are sustained through transfers from employed U.S. workers, then the after-tax income of working Americans will decline. This fear is one reason many

Americans oppose immigration of low-education, low-skilled workers to the United States.

Fiscal Impacts

What effects do immigrants have on tax revenues and government spending in the United States? Do they contribute to U.S. GDP, as our model suggests, or do they go on welfare and use "free" public goods, draining the government treasury?

Before the 1970s, the immigrant population was less likely to receive public assistance than people born in the United States. Migrants were typically young, single men with significant education and job training. They were readily employable in average-paying jobs and therefore were net contributors to the tax-expenditure system.

But the situation reversed between the 1970s and 1998, when immigrants began to use the welfare system proportionately more than natives. The changing mix of immigrants from relatively skilled workers toward unskilled workers explained the turnabout. Critics claimed that U.S. welfare programs were drawing unskilled (and often illegal) workers to the United States from some of the world's poorest nations. Immigrants made up more than 10 percent of Supplemental Security Income (SSI) rolls in 1998 compared to only 3.3 percent a decade before.

As a result of this trend, the major overhaul of the U.S. welfare system that was passed into law in 1996 denied welfare benefits to new legal immigrants for their first five years in the United States. As a result, between 1996 and 2006 cash welfare payments to immigrants declined by 73 percent, food stamps by 39 percent, and SSI payments by 20 percent.

It remained the case, however, that rates of welfare utilization continued to be higher among immigrants than nonimmigrants. In 2009, for instance, a survey of all households with minor children revealed that 57 percent of immigrant households used at least one form of welfare as compared with only 39 percent of nonimmigrant households. Among households headed by an illegal immigrant, the percentage stood even higher, at 71 percent.

In addition to utilizing welfare at high rates, low-income immigrants impose costs on state and local governments by enrolling children in public schools, using emergency health care facilities, and straining the criminal justice system. For low-income immigrants, these fiscal burdens substantially exceed taxes paid. We will say more about this later.

Research Findings

All economists agree that U.S. immigration increases U.S. domestic output and income and that highly educated immigrants and successful entrepreneurs add to the vitality of American enterprise. But in light of the complications just discussed, no single generalization is possible as to the impact of immigration on the wages of native-born U.S. workers.

The best evidence indicates that immigration reduces the wages of native-born workers who have low levels of education, and also may reduce the salaries of some highly trained native-born workers. For example, studies show that immigration reduces the wages of native-born Americans who do not have high school diplomas, native-born African American men, and native-born holders of doctorate degrees.

The overall effect of immigration on the average American wage is much less clear. Scholarly estimates on that effect range from minus 3 percent to plus 2 percent.³

QUICK REVIEW 25.2

- ✓ Other things equal, immigration reduces the average wage rate, increases domestic output, lowers the total wage income of native-born workers, and bolsters business income in the destination nation; it has the opposite effects in the origin nation.
- ✓ Assessing the impacts of immigration is complicated by such factors as remittances and backflows, complementary versus substitute labor, investment impacts, unemployment, and fiscal effects.

The Illegal Immigration Debate

L025.4 Relate how illegal immigration affects employment and wages in low-wage labor markets and impacts state and local budgets.

Much of the recent concern about immigration has focused on illegal immigration, not immigration per se. Economists point out that a strong inflow of undocumented workers to some extent reflects the increasing scarcity of domestic unskilled labor in the United States. Only about 12 percent of the native-born U.S. workforce has less than a high-school diploma today, compared to about 50 percent in 1960. That scarcity has created significant employment opportunities for unskilled illegal immigrants. Illegal workers make up roughly 26 percent of all agricultural workers, 24 percent of all cleaning workers, 20 percent of all employees in clothing manufacturing, and 14 percent of all construction workers.

Many Americans fear that illegal immigrants and their families depress wage rates in these and other already low-wage U.S. occupations and also burden American citizens through their use of public services such as emergency medical care and public schools. Are these concerns justified?

Employment Effects

Two extreme views on illegal immigration are often expressed. Some observers suggest that the employment of

illegal workers decreases the employment of legal workers on a one-for-one basis. They erroneously suggest that the economy has only a fixed number of jobs at any time. Supposedly, every job taken by an illegal worker deprives a legal resident of that job. At the other extreme is the claim that illegal workers accept only work that legal residents will not perform. Viewed this way, illegal workers displace *no* legal residents from their jobs.

Both views are misleading. Consider Figure 25.4, which illustrates a market for unskilled field workers in agriculture. The downsloping curve D is the labor demand curve for field workers. The upsloping supply curve S_d is the labor supply of domestic-born workers, while curve S_t reflects the combined total supply of domestic-born workers and illegal immigrants. The horizontal distances between S_t and S_d at the various wage rates measure the number of illegal immigrants offering their labor services at those wage rates.

With illegal workers present, as implied by curve S_t , the equilibrium wage and level of employment in this labor market are W_t and Q_t . At the low wage of W_t , only ab domestic-born workers are willing to work as field hands; the other workers— bd —are illegal immigrants. The low employment of domestic-born workers presumably is caused by their better wage opportunities and working conditions in alternative occupations or by the availability of government transfer payments. Recall that illegal workers are not eligible for most welfare benefits.

Can we therefore conclude from Figure 25.4 that illegal workers have filled field jobs that most U.S.-born workers do

FIGURE 25.4 The impacts of illegal workers in a low-wage labor market. Illegal workers in a low-wage labor market shift the labor supply curve, as from S_d to S_t , and reduce the market wage from W_d to W_t . At wage W_t , ab workers are domestic-born (or legal residents) and bd workers are illegal immigrants. If all the illegal workers were deported, however, Q_d American workers would be employed. To say that illegal workers do jobs that Americans are not willing to do (at any wage rate), therefore, is somewhat misleading. Similarly misleading is the conclusion that the deportation of illegal workers would boost the employment of American workers on a one-for-one basis.

³The research conclusions summarized in this section are based on recent studies conducted individually or jointly by several prominent economists, including George Borjas, David Card, Richard Freeman, Jeffrey Grogger, Gordon Hanson, Lawrence Katz, Gianmarco Ottaviano, and Giovanni Peri.

not want? The answer is “yes,” but only with the proviso: “at wage rate W_r .” With fewer illegal immigrants in this labor market, labor supply would be less than that shown by curve S_r . The wage rate would be higher than W_r , and more legal residents would offer their services as field hands. For example, if the United States cut off the full inflow of illegal workers to this market, the relevant supply curve would be S_d and the wage rate would rise to W_d . Then Q_d domestic-born workers as opposed to ab workers would work as field hands. The critical point is that the willingness of Americans to work at any particular job depends significantly on the wage rate being paid. A sufficiently high **compensating wage differential** (wage premium to compensate for undesirable work) will attract U.S. workers even to otherwise undesirable work.

The opposite argument, that illegal workers reduce the employment of Americans by an amount equal to the employment of illegal workers, is also misleading. Figure 25.4 reveals that the illegal workers increase the total number of jobs in the labor market. With illegal workers, the number of jobs is Q_r . Without those workers, it is only Q_d . The deportation of the illegal workers would not increase domestic employment on a one-for-one basis. Native-born employment would increase by the amount bc in this specific labor market, not by bd .

Generally, illegal immigration causes some substitution of illegal workers for domestic workers, but the amount of displacement is less than the total employment of the illegal workers. Illegal immigration—as with legal immigration—increases total employment in the United States.

Wage Effects

Large flows of illegal workers into specific low-wage labor markets reduce wage rates in those markets. Note in Figure 25.4 that the greater supply of field workers reduces their wage rate from W_d to W_r . Some U.S. wages—including those of field laborers, food preparers, and house cleaners—are lower than otherwise because of illegal immigration.

As discussed previously, the overall effect of illegal immigration on the average wage rate in the economy is either a smaller decline or even positive. As with legal immigrants, some illegal workers are complementary inputs to domestic-born workers, not substitutes. An example of this complementarity would be illegal fruit pickers and the domestic-born truck drivers who deliver the fruit to grocery stores. The lower price of the fruit increases the amount of fruit demanded and thus the amount of it that needs to be delivered. That increases the labor demand for the complementary truck drivers, whose wage rates rise.

Only where illegal workers and legal workers are substitute resources will the increase in labor supply reduce the wages of other workers. Ironically, studies show that the largest negative impact of illegal immigrants is on the wages of previous immigrants, not on those of native-born workers.

Illegal immigration has very little effect on the average level of wages in the United States. That average wage level depends mainly on the nation’s overall level of labor productivity, which illegal immigration does not appreciably affect.

Price Effects

Because illegal immigrants work at lower pay than would be necessary to attract native-born workers, the prices of goods and services that illegal workers produce are lower than they would be otherwise. The extent of such price reduction depends on several factors, including how much of the total cost of producing and delivering a product involves the services performed by illegal immigrants. In industries where illegal immigrants are heavily used—for example, construction, agriculture, landscaping, home cleaning, restaurant meals, and lodging—the presence of illegal workers may have a discernable downward price effect. Lower prices raise the standard of living of all Americans and their families.

Fiscal Impacts on Local and State Governments

One major and very legitimate concern about illegal immigration is the negative fiscal impact it has on local and state governments. Cities and states with high concentrations of illegal immigrants bear the main burden. The federal government receives the payroll taxes and income taxes withheld from the earnings of some illegal immigrants, but the state and local governments bear most of the costs of their presence. Immigrants place their children in local schools, use local emergency medical care, and add to the cost of the criminal justice system, most of which is provided by state and local governments. Immigrants do, however, pay state sales taxes and taxes on gasoline, and indirectly pay property taxes built into rent.

The average fiscal burden (government benefits minus taxes paid) on state and local government for each low-skilled immigrant household may be as high as \$19,500 per household per year. In 2006 about 40 percent of the 4.5 million households falling into this low-skilled category were headed by illegal immigrants. One recent estimate of the fiscal burden for these households as a group is nearly \$50 billion annually.

Other Concerns

Critics of illegal immigration point to other reasons to be concerned about illegal immigration. First, they say that allowing immigrants to enter the United States unlawfully undermines general respect for the law. If immigration laws can be broken, why can’t other laws also be broken? The success of many immigrants in entering the United States and working for employers illegally rests on other criminal activity such as the creation of fake birth certificates, Social Security cards, and

The Startling Slowdown in Illegal Immigration

Illegal Immigration Fell Precipitously during the 2007–2009 Recession. Why Did It Happen? And Will It Continue?

The number of illegal immigrants living in the United States more than tripled between 1990 and 2007, increasing from 3.5 million in 1990 to 12.2 million in 2007. But during the 2007–2009 recession, the trend reversed and the number of illegal immigrants living in the United States fell by nearly 8 percent, down to 11.3 million in 2009.

The decline occurred because the backflow of illegal immigrants returning to their home countries exceeded the inflow of illegal immigrants entering the United States. The most important underlying cause for the backflow exceeding the inflow was quite simple: decreased job prospects for illegal immigrants.

There had been a major boom in housing prices and new home construction during the early 2000s, but it peaked in 2006 before crashing in 2007. When it did, the demand for unskilled labor fell dramatically. The ensuing recession cut the demand for unskilled labor even further.

As a result, most economists concluded that illegal immigration had declined due to low employment demand. Following the same logic, they also assumed that when the economy picked up again, so would illegal immigration.

Thus, it was a major surprise when the overall size of the illegal immigrant population stayed steady at around 11.3 million not only immediately after the Great Recession of 2007–2009 but all the way through 2014 (the most recent year for which data are available). Economic growth had returned, but the net flow of illegal immigrants remained at about zero.

Economists have come up with several explanations for this leveling-off in the overall number of illegal immigrants. Taken together, they offer a plausible explanation for why illegal immigration remained subdued after the Great Recession—and for why it may decrease in coming years.

The first major factor has been the rapid decline in birth rates in the countries that have historically sent the most illegal immigrants to the United States. Consider Mexico. In 1960, Mexican women were having, on average, 7.3 births per woman per lifetime. By 2009, that number had tumbled to an average of just 2.4 births per lifetime—and, indeed, that number is expected to fall even further in coming years. As a result, the number of young

Mexicans entering the job market each year in Mexico is now far lower than it was just a decade ago. One result has been far fewer young Mexicans deciding to seek their fortunes in the United States.

At the same time, economic growth has picked up substantially in most of the countries that have traditionally sent the most illegal immigrants to the United States. Consider Mexico once again. Mexico's economy grew rapidly between 2010 and 2014. That rapid growth drove up local wages—thereby making the wages available in the United States seem relatively less attractive than they had seemed just a few years earlier.

Government policies have also played a role. The North American Free Trade Agreement (NAFTA) that was signed by the governments of Canada, Mexico, and the United States in 1992 cre-

ated a continent-wide free trade zone that spurred the creation of a larger manufacturing sector in Mexico. Mexico passed China and South Korea to become the world's largest producer of flat-screen TVs in 2009 and, in addition, Mexico has also become one of the world's top car and truck producers. Thus, many Mexicans now work in Mexican factories producing goods for export. Because they are employed in good-paying jobs in Mexico, they are less likely to want to immigrate illegally to the United States.

U.S. immigration-enforcement activities have also increased in recent years. A fence was built along several hundred miles of the U.S.-Mexican border and border patrols were strengthened after the 9/11 terrorist attack. As a result, the number of illegal immigrants deported by the U.S. Department of Homeland Security each year more than tripled between 2001 and 2014, rising from 189,026 removals in 2001 to 577,295 removals in 2014.

The factors just discussed—falling birth rates, better local job opportunities, and stronger border enforcement—lead many economists to conclude that illegal immigration is more likely to decrease than increase in coming years. If so, the debate over illegal immigration will likely take a less-prominent place in American political life. Whether one believes illegal immigration to be a serious problem or a net benefit, there will be less to argue over if the number of illegal immigrants declines in coming years.

driver's licenses. Also, some unauthorized immigrants engage in illegal activities such as drug smuggling, identity theft, and insurance fraud. Although legal U.S. immigrants have considerably lower incarceration rates than the native-born U.S. population, the crime rate for illegal immigrants is much higher than that of the native-born U.S. population.

Second, critics of the ineffective enforcement of border and employment laws point out that illegal immigration is highly unfair to the thousands of people enduring the expense and long waits associated with the process for legally gaining the right to live and work in the United States.

Finally, some observers see national defense as the greatest long-term risk from porous borders. The flow of illegal entrants into the United States is clearly at odds with the goal of homeland security. Ineffective border enforcement against illegal immigrants allows career criminals and even terrorists to enter the United States undetected.

QUICK REVIEW 25.3

- ✓ Illegal immigrants reduce wage rates in low-wage labor markets, take jobs that some Americans do not want, and expand total employment in low-wage occupations.
- ✓ The deportation of illegal immigrants would increase the wage rate in low-skilled labor markets but not increase employment on a one-to-one basis with the number of illegal workers deported.
- ✓ Illegal immigration imposes a high net fiscal burden on state and local governments.

Optimal Immigration

L025.5 Demonstrate how economics can inform current immigration discussions and attempts to reform immigration laws.

The immigration issues relating to quotas and illegal immigrants go well beyond economics. They are also political and cultural issues. Nevertheless, economics can help inform the debate. Economic analysis suggests that immigration can either benefit or harm a nation, depending on the number of immigrants; their education, skills, and work ethic; and the rate at which they can be absorbed into the economy without disruption.

From a strictly economic perspective, immigration should be expanded until its marginal benefit equals its marginal cost. The $MB = MC$ conceptual framework explicitly recognizes that there can be too few immigrants, just as there can be too many. Moreover, it recognizes that from a strictly economic standpoint, not all immigrants are alike. Some immigrants generate more benefits to the U.S. economy than others; and some immigrants impose more costs on taxpayers than others. The immigration of, say, a highly educated scientist obviously has a different net economic impact than does the immigration of a long-term welfare recipient.

A nation sets the level of legal immigration through quotas and special provisions. In effect, it also sets the size of illegal immigration through how effectively it secures its borders and enforces its immigration laws. This chapter's Last Word examines the surprising recent decline in illegal immigration into the United States and the various causes of that decline, including increased enforcement activities.

SUMMARY

L025.1 Describe the extent of legal and illegal immigration into the United States.

Legal immigrants may be either permanent immigrants (green card holders) or temporary immigrants who are legally in the country until a specific date. The United States admitted 990,553 legal permanent residents in 2013. About 55 percent of these immigrants were women; 45 percent were men. Roughly 58 percent of legal immigrants were married. The largest number of legal immigrants (135,028) was from Mexico, but Mexicans made up only 14 percent of the total number of legal immigrants in 2013. The vast majority of legal immigrants gain that status because of family ties with U.S. citizens and other legal residents.

Illegal immigrants (also called unauthorized immigrants, illegal aliens, or undocumented workers) are people who enter the country unlawfully or overstay their prescribed exit dates. An estimated 11.3 million illegal immigrants live in the United States. That number has held steady since 2009, with the net number of new arrivals and returns about equal. The vast majority of illegal immigrants come from Mexico.

L025.2 Discuss why economists view economic immigration as a personal human capital investment.

An economic migrant's decision to move to another country can be viewed as an investment, in which present sacrifices (explicit and implicit costs) are incurred to obtain larger lifetime gains (higher earnings). Other things equal, the shorter the distance of the move and the younger the potential economic migrant, the more likely the person will move to the destination country.

L025.3 Explain how immigration affects average wages, resource allocation, domestic output, and group income shares.

The simple immigration model suggests that, for a high-wage country, the movement of migrants from a low-wage country (*a*) increases domestic output (= domestic income), (*b*) reduces the average wage rate, (*c*) reduces the total wage income of native-born workers, and (*d*) increases business income. The opposite effects occur in the low-wage country. Because the domestic output gains in the high-wage country

exceed the domestic output losses in the low-wage country, labor resources are more efficiently allocated globally and world output rises.

The outcomes of immigration predicted by the simple immigration model become more complicated when considering (a) the costs of moving, (b) the possibility of remittances and backflows, (c) complementary rather than substitute labor, (d) impacts on investment, (e) the levels of unemployment in each country, and (f) the fiscal impact on the taxpayers of each country.

L025.4 Relate how illegal immigration affects employment and wages in low-wage labor markets and impacts state and local budgets.

Legal U.S. residents who have less than a high school education seem to bear the brunt of the wage impact of immigration, although some highly educated workers are also affected. Immigration has little discernible effect on the overall average wage rate in the U.S. economy, with estimates ranging from minus 3 percent to plus 2 percent.

Illegal workers in the United States reduce wage rates in narrowly defined low-wage labor markets, but they do not reduce native-born employment by the full extent of the employment of the illegal workers. American workers who are complementary to illegal immigrant labor may experience an increase in the demand for their services and wages because of the illegal immigrants.

L025.5 Demonstrate how economics can inform current immigration discussions and attempts to reform immigration laws.

Illegal workers may increase the overall rate of return on capital, thus promoting greater national investment. However, large numbers of illegal workers in specific industries may reduce the incentive for those industries to mechanize. A legitimate concern is that illegal workers and their families impose greater fiscal costs on state and local governments than they contribute in tax revenues to those jurisdictions.

DISCUSSION QUESTIONS

- Which of the following statements are true? Which are false? Explain why the false statements are untrue. **L025.1**
 - More immigrants arrive to the United States each year illegally than legally.
 - The majority of legal immigrants are men.
 - Over half the new legal immigrants to the United States each year are from Mexico.
 - Most legal immigrants to the United States gain their legal status through employment-based preferences.
- In what respect is the economic decision to move across international borders an investment decision? Why do economic migrants move to some countries but not to others? Cite an example of an explicit cost of moving; an implicit cost of moving. How do distance and age affect the migration decision? How does the presence of a large number of previous movers to a country affect the projected costs and benefits of subsequent movers? **L025.2**
- Suppose that the projected lifetime earnings gains from migration exceed the costs of moving. Explain how the decision to move might be reversed when a person considers present value. **L025.2**
- How might the output and income gains from immigration shown by the simple immigration model be affected by (a) unemployment in the originating nation, (b) remittances by immigrants to the home country, and (c) backflows of migrants to the home country? **L025.3**
- Suppose initially that immigrant labor and native-born labor are complementary resources. Explain how substantial immigration might change the demand for native-born workers, altering their wages. (Review the relevant portion of Chapter 16 if necessary to help answer this question.) Next, suppose that new immigrant labor and previous immigrant labor (not native-born) are substitute resources. Explain how substantial immigration of new workers might affect the demand for previous immigrants, altering their wages. **L025.3**
- What is a “brain drain” as it relates to international migration? If emigrants are highly educated and received greatly subsidized education in the home country, is there any justification for that country to levy a “brain drain” tax on them? Do you see any problems with this idea? **L025.3**
- In July 2007 *The Wall Street Journal* (*WSJ*) reported that a growing shortage of skilled labor in Eastern European countries such as Slovakia was driving up wages in key industries and reducing business income. The reason for the shortages was a large migration of skilled Eastern European workers to Western European countries. Use the simple immigration model to demonstrate the key elements of the *WSJ* story as just described. **L025.3**

8. Why is each of these statements somewhat misleading?
 (a) “Illegal immigrants take only jobs that no American wants.”
 (b) “Deporting 100,000 illegal immigrants would create 100,000 job openings for Americans.” **LO25.4**
9. Why are so many state and local governments greatly concerned about the federal government’s allegedly lax enforcement of the immigration laws and congressional proposals to grant legal status (amnesty) to the 11.3 million illegal immigrants in the United States? How might an amnesty program affect the flow of future border crossings? **LO25.5**
10. If someone favors the free movement of labor within the United States, is it inconsistent for that person to also favor restrictions on the international movement of labor? Why or why not? **LO25.5**
11. **LAST WORD** What was the single most important reason for the decline in illegal immigration between 2007 and 2009? What other factors were at play? Going forward, why might people think it more likely that illegal immigration will fall rather than rise?

REVIEW QUESTIONS

1. Each year, the number of legal immigrants to the United States is _____ the number of illegal immigrants. **LO25.1**
- Less than.
 - Equal to.
 - Greater than.
 - Less than, but only in *most* years, not every year.
2. The primary reason people immigrate to the United States is: **LO25.2**
- To escape political or religious oppression back home.
 - To reunite with family members.
 - To improve earnings and living standards.
 - None of the above.
3. True or False. Because older adults have more human capital, they are more likely to migrate to another country than younger adults. **LO25.2**
4. Use the accompanying tables for Neon and Zeon to answer the questions that follow. Assume that the wage rate shown equals hourly output and income, and that the accumulated output and income are the sum of the marginal revenue products (MRPs) of each worker. **LO25.3**

Neon

Workers	Wage Rate = MRP	Domestic Output and Income
1	\$21	\$ 21
2	19	40 (= 21 + 19)
3	17	57 (= 21 + 19 + 17)

- Which country has the greater stock of capital and technological prowess? How can you tell?
 - Suppose the equilibrium wage rate is \$19 in Neon and \$7 in Zeon. What is the domestic output (= domestic income) in the two countries?
 - Assuming zero migration costs and initial wage rates of \$19 in Neon and \$7 in Zeon, how many workers will move to Neon? Why will not more than that number of workers move to Neon?
 - After the move of workers, what will the equilibrium wage rate be in each country? What will the domestic output be after the migration? What is the amount of the combined gain in domestic output produced by the migration? Which country will gain output; which will lose output? How will the income of native-born workers be affected in each country?
5. Migration between North Korea and South Korea has been prohibited since the end of the Korean War in 1953. South Korea is now much richer than North Korea and has a much higher marginal product of labor and a much higher wage rate than North Korea. If workers could migrate from North Korea to South Korea, we would expect: **LO25.3**
- Output to fall in South Korea but rise in North Korea.
 - Output to rise in each country.
 - Total combined output in the two countries to fall.
 - Total combined output in the two countries to rise.
6. True or False. Research indicates that immigration causes large decreases in the average American wage. **LO25.3**
7. True or False. The $MB = MC$ level of immigration is likely to be achieved if we simply let in every person who wishes to immigrate to the United States. **LO25.5**

PROBLEMS

1. Mexico has daily (rather than hourly) minimum wage laws. In 2016, the daily minimum wage in Mexico was about 73 pesos per day, and the exchange rate between Mexican pesos and U.S. dollars was about 17 pesos per dollar. **L025.3**
 - a. In 2016, what was the Mexican minimum daily wage in terms of dollars?
 - b. Given that Mexican employees typically work 8-hour days, about how much *per hour* is the Mexican minimum wage in terms of dollars?
 - c. In 2016, the federal minimum wage in the United States was \$7.25 per hour. How many times larger was the hourly U.S. federal minimum wage than the hourly Mexican minimum wage?
 - d. If unskilled workers have a tendency to migrate to where they can obtain the highest compensation for their labor, which country is more likely to be receiving low-skilled immigrants?
2. Differences in productivity are usually the major force behind differences in wages and unit labor costs. Suppose that a single unskilled worker at a pottery factory in Mexico can produce 1 mug per hour. By comparison, suppose that a single unskilled worker at a pottery factory in the United States can produce 14 mugs per hour because more and better machinery generates higher labor productivity. The Mexican mugs and the American mugs are identical in quality and durability and sell for the same price. **L025.3**
 - a. If unskilled pottery workers are paid the local minimum wage in both countries, how much is the labor cost *per mug* for mugs produced in Mexico? For mugs produced in the United States? (Use the minimum wages from problem 1 and make all calculations in dollars.)
 - b. With regard to mug production, how much higher are labor costs *per hour* in the United States?
 - c. With regard to mug production, how much higher are labor costs *per unit* in Mexico?
 - d. Do higher labor costs per hour always imply higher labor costs per unit?
 - e. If firms with lower labor costs per unit expand, while those with higher labor costs per unit contract, in which country will mug-making firms be increasing in size and hiring more employees? If unskilled pottery workers relocate to where they can find jobs, to which country will they be moving?
3. There is evidence that, other things equal, a 10 percent increase in the number of workers having a particular skill level leads to about a 4 percent decline in wages for workers with that skill level. In addition, this 10-to-4 ratio appears to hold true whether the increase in labor supply is caused by domestic changes in labor supply or by an influx of foreign immigrants. **L025.3**
 - a. Suppose that 42,000 computer programmers work in Silicon Valley. If the number of computer programmers in Silicon Valley increases by 1,260 because of a change in U.S. immigration laws, by how many percentage points would you expect the wage of computer programmers to fall in Silicon Valley?
 - b. Suppose that 8,000 full-time cooks work in restaurants in the Denver area. If Denver becomes popular both with U.S. citizens and with foreigners such that 400 full-time cooks move to Denver from other parts of the United States while 80 full-time cooks move to Denver from other countries, by how much would you expect the wages of full-time cooks to fall in Denver?
4. In 2012, an estimated 7.8 million Mexican-born immigrants were employed in the United States. **L025.3**
 - a. If 60 percent of the Mexican-born immigrants remitted money to family members in Mexico in 2012, and if they each sent \$100 per month, how much money did they remit in total?
 - b. If, instead, 100 percent of the Mexican-born immigrants remitted money to family members in Mexico in 2012, and if they each sent \$250 per month, how much money did they remit in total?
 - c. The actual amount remitted to Mexico in 2012 by Mexican-born immigrants living in the United States was about \$23 billion. If we assume that 75 percent of the Mexican-born immigrants remitted money to Mexico that year and if we further assume that each of those immigrants remitted an equal amount each month, how much per month did each of those immigrants have to remit to total \$23 billion for the year?

An Introduction to Macroeconomics

Learning Objectives

- LO26.1** Explain why economists focus on GDP, inflation, and unemployment when assessing the health of an entire economy.
- LO26.2** Discuss why sustained increases in living standards are a historically recent phenomenon.
- LO26.3** Identify why saving and investment are key factors in promoting rising living standards.
- LO26.4** Describe why economists believe that “shocks” and “sticky prices” are responsible for short-run fluctuations in output and employment.
- LO26.5** Characterize the degree to which various prices in the economy are sticky.
- LO26.6** Explain why the greater flexibility of prices as time passes causes economists to utilize different macroeconomic models for different time horizons.

Macroeconomics focuses its attention on national economies while seeking answers to the largest of economic questions. For instance: Why are some countries really

rich while others are really poor? Why do some countries enjoy sustained, long-run increases in living standards, while other countries simply stagnate? Why do all countries—even the richest—go through alternating boom and bust periods? And is there anything that governments can do to improve living standards or fight recessions?

This chapter provides an overview of the data that macroeconomists use to measure the status and growth of an entire economy as well as a preview of the models that they use to help explain both long-run growth and short-run fluctuations. Because it is an overview chapter, it raises many unanswered questions. Subsequent chapters will explain these topics in much greater detail.

Performance and Policy

LO26.1 Explain why economists focus on GDP, inflation, and unemployment when assessing the health of an entire economy. As you know from Chapter 1, macroeconomics studies the behavior of the economy as a whole. It is primarily concerned with two topics: long-run economic growth and the short-run fluctuations in output and employment that are often referred to as the **business cycle**. These phenomena are closely related because they happen simultaneously. Economies show a distinct growth trend that leads to higher output and higher

standards of living in the long run, but in the short run there is considerable variability. Sometimes growth proceeds more rapidly and sometimes it proceeds more slowly. It may even turn negative for a while so that output and living standards actually decline, a situation referred to as a **recession**. That is precisely what happened in late 2007 and continued through 2008 and into 2009. The economy experienced what has come to be called the Great Recession.

To understand how economies operate and how their performance might be improved, economists collect and analyze economic data. An almost infinite number of data items can be looked at, including the amount of new construction taking place each month, how many ships laden with cargo are arriving at our ports each year, and how many new inventions have been patented in the last few weeks. That being said, macroeconomists tend to focus on just a few statistics when trying to assess the health and development of an economy. Chief among these are real GDP, unemployment, and inflation.

- **Real GDP, or real gross domestic product**, measures the value of final goods and services produced within the borders of a country during a specific period of time, typically a year. This statistic is very useful because it can tell us whether an economy's output is growing. For instance, if U.S. real GDP in one year is larger than in the previous year, we know that U.S. output increased from the first year to the next. To determine real GDP, government statisticians first calculate **nominal GDP**, which totals the dollar value of all goods and services produced within the borders of a country using *their current prices during the year that they were produced*. But because nominal GDP uses the prices in place in the year the output was produced, it suffers from a major problem: It can increase from one year to the next even if there is no increase in output. To see how, consider a commercial blacksmith who produced 10 iron spiral staircases last year and 10 identical staircases this year. Clearly, the blacksmith's output did not change. But if the price of each staircase rose from \$10,000 last year to \$20,000 this year, nominal GDP increased from \$100,000 ($= 10 \times \$10,000$) to \$200,000 ($= 10 \times \$20,000$). Without knowing about the price increase, we might unwisely conclude that the output of staircases increased from 10 to 20. Real GDP statistically eliminates these kinds of price changes. As a result, we can compare real GDP numbers from one year to the next and really know if there is a change in output (rather than prices). Because more output means greater consumption possibilities—including not only the chance to consume more fun things such as movies, vacations, and video games, but also more serious things like better health care and safer roads—economists and

policymakers are deeply committed to encouraging a large and growing real GDP.

- **Unemployment** is the state a person is in if he or she cannot get a job despite being willing to work and actively seeking work. High rates of unemployment are undesirable because they indicate that a nation is not using a large portion of its most important resource—the talents and skills of its people. Unemployment is a waste because we must count as a loss all the goods and services that unemployed workers could have produced if they had been working. Researchers have also drawn links between higher rates of unemployment and major social problems like higher crime rates and greater political unrest as well as higher rates of depression, heart disease, and other illnesses among unemployed individuals.
- **Inflation** is an increase in the overall level of prices. As an example, consider all the goods and services bought by a typical family over the course of one year. If the economy is experiencing inflation, it will cost the family more money to buy those goods and services this year than it cost to buy them last year. This can be troublesome for several reasons. First, if the family's income does not rise as fast as the prices of the goods and services that it consumes, it won't be able to purchase as much as it used to and its standard of living will fall. Along the same lines, a surprise jump in inflation reduces the purchasing power of people's savings. Savings that they believed would be able to buy them a specific amount of goods and services will turn out to buy them less than they expected due to the higher-than-expected prices.

Because these statistics are the standards by which economists keep track of long-run growth and short-run fluctuations, we will spend a substantial amount of time in the next few chapters examining how these statistics are computed, how well they are able to capture the well-being of actual people, and how they vary both across countries and over time. Once they are understood, we will build on them in subsequent chapters by developing macroeconomic models of both long-run growth and short-run fluctuations. These will help us understand how policymakers attempt to maximize growth while minimizing unemployment and inflation.

Macroeconomic models also clarify many important questions about the powers and limits of government economic policy. These include:

- Can governments promote long-run economic growth?
- Can they reduce the severity of recessions by smoothing out short-run fluctuations?
- Are certain government policy tools such as manipulating interest rates (monetary policy) more effective at

mitigating short-run fluctuations than other government policy tools such as changes in tax rates or levels of government spending (fiscal policy)?

- Is there a trade-off between lower rates of unemployment and higher rates of inflation?
- Does government policy work best when it is announced in advance or when it is a surprise?

The answers to these questions are of crucial importance because of the vast differences in economic performance experienced by national economies at different times. For instance, the amount of output generated by the U.S. economy grew at an average rate of 2.7 percent per year between 1995 and the start of the recession of 2007–2009, while the amount of output generated by the Japanese economy grew at an average rate of only 1.0 percent per year over the same time period. In 2008 and 2009, however, the U.S. economy lost 8 million jobs, and the unemployment rate rose from 4.6 percent to as high as 10.1 percent. In 2015, after more than a half-decade of recovery, the unemployment rate was 5.3 percent in the United States, 25.0 percent in Greece, 3.6 percent in South Korea, 10.4 percent in France, and 40.6 percent in Haiti. At the same time, the inflation rate was 0.1 percent in the United States, 2.2 percent in Norway, 2.7 percent in Mexico, 6.6 percent in Kenya, and a very high 121.7 percent in Venezuela.

Our models will help us understand why such large differences in rates of growth, unemployment, and inflation exist among countries and why those rates can change so substantially from one period to another. These models also will provide significant insights on how government policies can influence rates of growth, unemployment, and inflation.

QUICK REVIEW 26.1

- ✓ Macroeconomists focus their attention on three key economic statistics: real GDP, unemployment, and inflation.
- ✓ Macroeconomic models help to clarify many important questions about government economic policy.

The Miracle of Modern Economic Growth

L026.2 Discuss why sustained increases in living standards are a historically recent phenomenon.

Rapid and sustained economic growth is a modern phenomenon. Before the Industrial Revolution began in the late 1700s in England, standards of living showed virtually no growth over hundreds or even thousands of years. For instance, the

standard of living of the average Roman peasant was virtually the same at the start of the Roman Empire around the year 500 B.C. as it was at the end of the Roman Empire 1,000 years later. Similarly, historians and archaeologists have estimated that the standard of living enjoyed by the average Chinese peasant was essentially the same in the year A.D. 1800 as it was in the year A.D. 100.

That is not to say that the Roman and Chinese economies did not expand over time. They did. In fact, their total outputs of goods and services increased many times over. The problem was that as they did, their populations went up by similar proportions so that the amount of output *per person* remained virtually unchanged.

This historical pattern continued until the start of the Industrial Revolution, which ushered in not only factory production and automation but also massive increases in research and development so that new and better technologies were constantly being invented. The result was that output began to grow faster than the population. This meant that living standards began to rise as the amount of output *per person* increased.

Not all countries experienced this phenomenon, but those that did were said to be experiencing **modern economic growth** (in which output per person rises) as compared with earlier times in which output (but not output per person) increased. Under modern economic growth, the annual increase in output per person is often not large, perhaps 2 percent per year in countries such as England that were the first to industrialize. But when compounded over time, an annual growth rate of 2 percent adds up very rapidly. Indeed, it implies that the standard of living will double every 35 years. So if the average citizen of a country enjoying 2 percent growth begins this year with an income of \$10,000, in 35 years that person will have an income of \$20,000. And 35 years after that there will be another doubling so that her income in 70 years will be \$40,000. And 35 years after that, the average citizen's income will double again to \$80,000. Such high rates of growth are amazing when compared to the period before modern economic growth when standards of living remained unchanged century after century.

The vast differences in living standards seen today between rich and poor countries are almost entirely the result of the fact that only some countries have experienced modern economic growth. Indeed, before the start of the Industrial Revolution in the late 1700s, living standards around the world were very similar, so much so that the average standard of living in the richest parts of the world was at most only two or three times higher than the standard of living in the poorest parts of the world. By contrast, the citizens of the richest nations today have material standards of living that are on average more than 50 times higher than those experienced by citizens of the poorest nations, as can be seen by the GDP per person data for the year 2011 given in Global Perspective 26.1.

Global Perspective 26.1 facilitates international comparisons of living standards by making three adjustments to each country's GDP. First, it converts each country's GDP from its own currency into U.S. dollars so that there is no confusion about the values of different currencies. Second, it divides each country's GDP measured in dollars by the size of its population. The resulting number, *GDP per person*, is the average amount of output each person in each country could have if each country's total output were divided equally among its citizens. It is a measure of each country's average standard of living. Third, the table uses a method called *purchasing power parity* to adjust for the fact that prices are much lower in some countries than others. By making this adjustment, we can trust that \$1 of GDP per person in the United States represents about the same quantity of goods and services as \$1 of GDP per person in any of the other countries. The resulting numbers—GDP per person adjusted for purchasing power parity—are presented in Global Perspective 26.1.

QUICK REVIEW 26.2

- ✓ Before the Industrial Revolution, living standards did not show any sustained increases over time because any increase in output tended to be offset by an equally large increase in population.
- ✓ Since the Industrial Revolution, many nations have experienced *modern economic growth* in which output grows faster than population—so that living standards rise over time.

Saving, Investment, and Choosing between Present and Future Consumption

LO26.3 Identify why saving and investment are key factors in promoting rising living standards.

At the heart of economic growth is the principle that to raise living standards over time, an economy must devote at least some fraction of its current output to increasing future output. As implied in Chapter 1, this process requires flows of both saving and investment, which we will define and discuss before returning to why they are so important for economic growth.

- **Saving** occurs when current consumption is less than current output (or when current spending is less than current income).
- **Investment** happens when resources are devoted to increasing future output—for instance by building a new research facility in which scientists invent the next generation of fuel-efficient automobiles or by constructing a modern, super-efficient factory. (A caution: In economics, the term “investment” differs from common usage. To understand why, be sure to read the nearby Consider This box.)

When thinking about why saving and investment are so important for economic growth, the key point is that the amount of investment is ultimately limited by the amount of saving. The only way that more output can be directed at investment activities is if saving increases. But that, in turn, implies that individuals and society as a whole must make trade-offs between current and future consumption. This is true because the only way to pay for more investment—and the higher levels of future consumption that more investment can generate—is to increase present saving. But increased saving can only come at the price of reduced current consumption. Individuals and society as a whole must therefore wrestle with a choice between present consumption and future consumption. They must decide how to balance the reductions in current consumption required to fund current investment against the increases in future consumption that the added current investment will make possible.

Economic versus Financial Investment

Economics students often are confused by how the word “investment” is used in economics. This is understandable, be-

cause economists draw a distinction between “financial investment” and “economic investment.”

Financial investment captures what ordinary people mean when they say investment, namely, the purchase of assets like stocks, bonds, and real estate in the hope of reaping a financial gain. Anything of monetary value is an asset and, in everyday usage, people purchase—or “invest” in—assets hoping to receive a financial gain, either by eventually selling them at higher prices than they paid for them or by receiving a stream of payments from others who are allowed to use the asset. By contrast, when economists say “investment,” they are referring to **economic investment**, which relates to the creation and expansion of business enterprises. Specifically, economic investment only includes spending on the production and accumulation of newly created capital goods such as machinery, tools, factories, and warehouses. For example, economic investment will occur when the airplane shown in the accompanying photo is purchased by a commercial airline.

For economists, purely financial transactions, such as swapping cash for a stock or a bond, are not “investment.” Neither are the purchases of factories or apartment buildings built in previous years. These transactions simply transfer the ownership of financial assets or existing real assets from one party to another. They do not purchase newly created capital goods. As such, they are great examples of financial investment, but not of economic investment. So now that you know the difference, remember that purely financial transactions, like buying Google stock or a five-year-old factory, are indeed referred to as “investment”—except in economics!

Banks and Other Financial Institutions

Households are the principal source of savings. But businesses are the main economic investors. So how does the pool of savings generated by households when they spend less than they consume get transferred to businesses so that they can purchase newly created capital goods? The answer is through banks and other financial institutions such as mutual funds, pension plans, and insurance companies. These institutions collect the savings of households, rewarding savers with interest and dividends and sometimes capital gains (increases in asset values). The banks and other financial institutions

then lend the funds to businesses, which invest in equipment, factories, and other capital goods.

Macroeconomics devotes considerable attention to money, banking, and financial institutions because a well-functioning financial system helps to promote economic growth and stability by encouraging saving and by properly directing that saving into the most productive possible investments. In contrast, a poorly functioning financial system can create serious problems for an economy.

QUICK REVIEW 26.3

- ✓ An economy can only grow if it invests, and it can only invest if it saves some of its current output. Thus, saving is crucial to increasing investment and, consequently, future output.
- ✓ Banks and other financial institutions channel household savings toward businesses, which invest in equipment, factories, and other capital goods.

Uncertainty, Expectations, and Shocks

L026.4 Describe why economists believe that “shocks” and “sticky prices” are responsible for short-run fluctuations in output and employment.

Decisions about savings and investment are complicated by the fact that the future is uncertain. Investment projects sometimes produce disappointing results or even fail totally. As a result, firms spend considerable time trying to predict future trends so that they can, hopefully, invest only in projects that are likely to succeed. This implies that macroeconomics has to take into account **expectations** about the future.

The Importance of Expectations and Shocks

Expectations are hugely important for two reasons. The more obvious reason involves the effect that changing expectations have on current behavior. If firms grow more pessimistic about the future returns that are likely to come from current investments, they are going to invest less today than they would if they were more optimistic. Expectations therefore have a large effect on economic growth since increased pessimism will lead to less current investment and, subsequently, less future consumption.

The less-obvious reason that expectations are so important has to do with what happens when expectations are unmet. Firms are often forced to cope with **shocks**—situations in which they were expecting one thing to happen but then something else happened. For instance, consider a situation in which a firm decides to build a high-speed railroad that will shuttle passengers between Los Angeles and Las Vegas.

The firm expects it to be very popular and make a handsome profit. But if it unexpectedly turns out to be unpopular and loses money, the railroad must figure out how to respond. Should the railroad go out of business completely? Should it attempt to see if it can turn a profit by hauling cargo instead of passengers? Is there a possibility that the venture might succeed if the firm borrows \$30 million from a bank to pay for a massive advertising campaign? These sorts of decisions are necessitated by the shock and surprise of having to deal with an unexpected situation.

Economies are exposed to both demand shocks and supply shocks. **Demand shocks** are unexpected changes in the demand for goods and services. **Supply shocks** are unexpected changes in the supply of goods and services. Note that the word *shock* only reveals that something unexpected has happened. It does not tell us whether what has happened is unexpectedly good or unexpectedly bad. To clarify this, economists use more specific terms. For instance, a *positive demand shock* refers to a situation in which demand turns out to be higher than expected, while a *negative demand shock* refers to a situation in which demand turns out to be lower than expected.

Demand Shocks and Sticky Prices

Economists believe that most short-run fluctuations in GDP and the business cycle are the result of demand shocks. Supply shocks do happen in some cases and are very important when they do occur. But we will focus most of our attention in this chapter and subsequent chapters on demand shocks, how they affect the economy, and how government policy may be able to help the economy adjust to them.

But why are demand shocks such a big problem? Why would we have to consider calling in the government to help deal with them? And why can't firms deal with demand shocks on their own?

The answer to these questions is that the prices of many goods and services are inflexible (slow to change, or "sticky") in the short run. As we will explain, this implies that price changes do not quickly equalize the quantities demanded of such goods and services with their respective quantities supplied. Instead, because prices are inflexible, the economy is forced to respond in the short run to demand shocks primarily through changes in output and employment rather than through changes in prices.

Example: A Single Firm Dealing with Demand Shocks and Sticky Prices

Although an economy as a whole is vastly more complex than a single firm, an analogy that uses a single car factory will be helpful in explaining why demand shocks and inflexible prices are so important to understanding most of the

short-run fluctuations that affect the entire economy. Consider a car manufacturing company named Buzzer Auto. Like most companies, Buzzer Auto is in business to try to make a profit. Part of turning a profit involves trying to develop accurate expectations about future market conditions. Consequently, Buzzer constantly does market research to estimate future demand conditions so that it will, hopefully, only build cars that people are going to want to buy.

Setting Expectations After extensive market research, Buzzer concludes that it could earn a modest profit if it builds and staffs an appropriately sized factory to build an environmentally friendly SUV, which it decides to call the Prion. Buzzer's marketing economists collaborate with Buzzer's engineers and conclude that expected profits will be maximized if the firm builds a factory that has an optimal output rate of 900 cars per week. If the factory operates at this rate, it can produce Prions for only \$36,500 per vehicle. This is terrific because the firm's estimates for demand indicate that a supply of 900 vehicles per week can be sold at a price of \$37,000 per vehicle—meaning that if everything goes according to plan, Buzzer Auto should make an accounting profit of \$500 on each Prion that it produces and sells. Expecting these future conditions, Buzzer decides to build the factory, staff it with workers, and begin making the Prion.

Look at Figure 26.1a, which shows the market for Prions when the vertical supply curve for Prions is fixed at the factory's optimal output rate of 900 cars per week. Notice that we have drawn in three possible demand curves. D_L corresponds to low demand for the Prion, D_M corresponds to the medium level of demand that Buzzer's marketing economists are expecting to materialize, and D_H corresponds to high demand for the Prion. Figure 26.1a is consistent with the marketing economists' expectations: If all goes according to plan and the actual demand that materializes is D_M , the equilibrium price will in fact be \$37,000 per Prion and the equilibrium quantity demanded will be 900 cars per week. Thus, if all goes according to expectations, the factory will have exactly the right capacity to meet the expected quantity demanded at the sales price of \$37,000 per vehicle. In addition, the firm's books will show a profit of \$500 per vehicle on each of the 900 vehicles that it builds and expects to sell each week at that price.

Full Employment if There Are No Shocks Here is the key point. If expectations are always fulfilled, Buzzer Auto will never contribute to any of the short-run fluctuations in output and unemployment that affect real-world economies. First, if everything always goes according to plan and Buzzer Auto's expectations always come true, then the factory will always produce and sell at its optimal output rate of 900 cars per week. This would mean that it would never experience any fluctuations in output—either in the short run or in the long run.

FIGURE 26.1 The effect of unexpected changes in demand under flexible and fixed prices. (a) If prices are flexible, then no matter what demand turns out to be, Buzzer Auto can continue to sell its optimal output of 900 cars per week since the equilibrium price will adjust to equalize the quantity demanded with the quantity supplied. (b) By contrast, if Buzzer Auto sticks with a fixed-price policy, then the quantity demanded will vary with the level of demand. At the fixed price of \$37,000 per vehicle, the quantity demanded will be 700 cars per week if demand is D_L , 900 cars per week if demand is D_M , and 1,150 cars per week if demand is D_H .

At the same time, since producing a constant output of 900 cars each week will always require the same number of workers, the factory's labor demand and employment should never vary. So if everything always goes according to plan, Buzzer Auto will never have any effect on unemployment because it will always hire a constant number of workers.

These facts imply that the short-run fluctuations in output and unemployment that we do see in the real world must be the result of shocks and things *not* going according to plan. In particular, business cycle fluctuations typically arise because the actual demand that materializes ends up being either lower or higher than what people were expecting. When this occurs, some adjustments will be necessary to bring quantity demanded and quantity supplied back into alignment. As we are about to explain, the nature of these adjustments varies hugely depending on whether prices are flexible or inflexible.

Price Changes if There Are Demand Shocks and Flexible Prices Figure 26.1a illustrates the case of adjusting to unexpected changes in demand *when prices are flexible*. Here, if demand is unexpectedly low at D_L , the market price can adjust downward to \$35,000 per vehicle so that the quantity demanded at that price will still be equal to the factory's optimal output rate of 900 cars per week. On the other hand, if demand is unexpectedly high at D_H , the market price can adjust upward to \$40,000 per vehicle so that the

quantity demanded will still be equal to the factory's optimal output rate of 900 cars per week. These adjustments imply that *if* the price of Prions is free to quickly adjust to new equilibrium levels in response to unexpected changes in demand, the factory could always operate at its optimal output rate of 900 cars per week. Only the amount of profit or loss will vary with demand.

Applying this logic to the economy as a whole, *if* the prices of goods and services could always adjust quickly to unexpected changes in demand, then the economy could always produce at its optimal capacity since prices would adjust to ensure that the quantity demanded of each good and service would always equal the quantity supplied. Simply put, if prices were fully flexible, there would be no short-run fluctuations in output. Production levels would remain constant and unemployment levels would not change because firms would always need the same number of workers to produce the same amount of output.

Output Changes if There Are Demand Shocks and Sticky Prices In reality, many prices in the economy are inflexible and are not able to change rapidly when demand changes unexpectedly. Consider the extreme case shown in Figure 26.1b, in which the price of Prions is totally inflexible, fixed at \$37,000 per Prion. Here, if demand unexpectedly falls from D_M to D_L , the quantity demanded at the fixed price of \$37,000 will only be 700 cars per week, which is 200 cars

fewer than the factory's optimal output of 900 cars per week. On the other hand, if demand is unexpectedly high at D_H , the quantity demanded at the fixed price of \$37,000 will be 1,150 cars per week, which is 250 cars more than the factory's optimal output of 900 cars per week.

One way for companies to deal with these unexpected shifts in quantity demanded would be to try to adjust the factory's output to match them. That is, during weeks of low demand, Buzzer Auto could attempt to produce only 700 Prions, while during weeks of high demand it could try to produce 1,150 Prions. But this sort of flexible output strategy is very expensive because factories operate at their lowest costs when they are producing constantly at their optimal output levels; operating at either a higher or a lower production rate results in higher per-unit production costs.¹

Knowing this, manufacturing firms typically attempt to deal with unexpected changes in demand by maintaining an inventory. An **inventory** is a store of output that has been produced but not yet sold. Inventories are useful because they can be allowed to grow or decline in periods when demand is unexpectedly low or high—thereby allowing production to proceed smoothly even when demand is variable. In our example, Buzzer Auto would maintain an inventory of unsold Prions. In weeks when demand is unexpectedly low, the inventory will increase by 200 Prions as the quantity demanded falls 200 vehicles short of the factory's optimal output. By contrast, during weeks when demand is unexpectedly high, the inventory will decrease as the quantity demanded exceeds the factory's optimal output by 250 cars. By allowing inventory levels to fluctuate with these unexpected shifts in demand, Buzzer Auto can respond by adjusting inventory levels rather than output levels. In addition, with any luck, the overall inventory level will stay roughly constant over time as unexpected increases and decreases in demand cancel each other out.

But consider what will happen if the firm experiences many successive weeks of unexpectedly low demand. For each such week, the firm's inventory of unsold Prions will increase by 200 cars. The firm's managers will not mind if this happens for a few weeks, but if it continues for many weeks, then the managers will be forced to cut production because, among other things, there will simply be no place to park so many unsold vehicles. More importantly, holding large numbers of unsold cars in inventory is unprofitable because while costs must be incurred to build an unsold car, an unsold car obviously brings in no revenue. Constantly rising inventories hurt firm profits and the management will want to reduce output if it sees inventories rising week after week due to unexpectedly low demand.

¹If you have studied microeconomics, you will recognize that the firm's optimal output level of 900 cars per week is the level that minimizes the factory's average total cost (ATC) per vehicle of producing the Prion. Producing either more or fewer Prions will result in higher per-vehicle production costs.

Generalizing from a Single Firm to the Entire Economy

This simplified story about a single car company explains why economists believe that a combination of unexpected changes in demand and inflexible prices are the key to understanding the short-run fluctuations that affect real-world economies. If prices were flexible, then the firm could always operate at the factory's optimal output level because prices would always adjust to ensure that it could sell its optimal output of 900 cars per week no matter what happens to demand. But if prices are inflexible, then an unexpected decline in demand that persists for any length of time will result in increasing inventories that will eventually force the firm's management to cut production to less than the optimal output level of 900 cars per week. When this happens, not only will output fall, but unemployment will also rise. The firm will lay off workers because fewer employees will be needed to produce fewer cars.

Generalizing this story to the economy as a whole, if demand falls off for many goods and services across the entire economy for an extended period of time, then the firms that make those goods and services will be forced to cut production. Manufacturing firms that maintain inventories will do so as they find inventories piling up due to sluggish sales. And services firms will do so as they encounter slow sales for their services. As both manufacturing and service output declines, the economy will recede, with GDP falling and unemployment rising.

On the other hand, if demand is unexpectedly high for a prolonged period of time, the economy will boom and unemployment will fall. In the case of our Prion example, for each week that demand is unexpectedly high, inventories will fall by 250 cars. If this keeps happening week after week, inventories will start to run out and the firm will have to react by increasing production to more than the optimal output rate of 900 cars per week so that orders do not go unfilled. When this happens, GDP will increase as more cars per week are produced and unemployment will fall because the factory will need to hire more workers to produce the larger number of cars.

QUICK REVIEW 26.4

- ✓ Economic shocks occur when events unfold in ways that people were not expecting.
- ✓ Demand and supply shocks take place when demand or supply ends up being either higher or lower than expected.
- ✓ Real-world prices are often inflexible or “sticky” in the short run.
- ✓ When prices are sticky, the economy adjusts to demand shocks mostly through changes in output and employment (rather than through changes in prices).

The Great Recession

In 2008 and 2009, the United States encountered its worst financial and economic crisis since the Great Depression of the 1930s.

The recession was so severe that it has been dubbed the Great Recession. The recession was triggered by a steep decline in housing prices and a crisis involving mortgage loans and the financial securities built on them. Several key U.S. financial institutions collapsed or nearly failed, and lending markets largely froze. Despite government bailout efforts, the financial crisis eventually spread to the broader economy. Employment fell by 8 million workers between 2007 and the end of 2009, and the unemployment rate rose from 4.6 percent to 10.1 percent over that same period. Economic growth slumped to 0.4 percent in 2008 and to a *negative* 2.4 percent in 2009, compared with the 2.7 percent annual increases occurring between 1995 and 2007.

And this is where Buzzer Auto comes into the picture. The situation in Figure 26.1b, where the price of Buzzer's autos is inflexible, is highly relevant to the Great Recession. Like Buzzer, actual auto producers such as GM, Ford, and Chrysler, as well as thousands of producers of other products across the economy, established their production capacity and set their expectations of product demand on the basis of normal times. But demand for their goods and services fell unexpectedly because of greater consumer difficulty in getting loans, declining consumer confidence, and eventually declining income. The economy's price level (essentially a weighted average of all prices) declined only slightly, and that was after the recession was well under way. Therefore, real output (not prices) took the major brunt of the decline of total demand in the economy. Output dropped, employment plummeted, and unemployment soared.

How Sticky Are Prices?

LO26.5 Characterize the degree to which various prices in the economy are sticky.

We have just shown that **inflexible prices**—or “**sticky prices**” as economists are fond of saying—help to explain how unexpected changes in demand lead to the fluctuations in GDP and employment that occur over the course of the business cycle. Of course, not all prices are sticky. Indeed, the markets for many commodities and raw materials such as corn, oil, and natural gas feature extremely **flexible prices** that react within seconds to changes in supply and

demand. By contrast, the prices of most of the final goods and services that people consume are quite sticky, with the average good or service going 4.3 months between price changes. To get a better appreciation for the fact that price stickiness varies greatly by product or service, look at Table 26.1, which gives the average number of months between price changes for various common goods and services. The prices of some products like gasoline and airline tickets change very rapidly—about once a month or even less than once a month. By contrast, haircuts and newspapers average more than two years between price changes. And coin-operated laundry machines average nearly four years between price changes!

An important recent study has found that product prices are particularly sticky in response to widespread macroeconomic and monetary disturbances.² In later chapters, we will identify and discuss several factors that cause short-run price stickiness. But to keep the current discussion brief, let's focus on just two factors here. One factor is that companies selling final goods and services know that consumers prefer stable, predictable prices that do not fluctuate rapidly with changes in demand. Consumers would be annoyed if the same bottle of soda or shampoo cost one price one day, a different price the next day, and yet another price a week later. Volatile prices make planning more difficult, and, in addition, consumers who come in to buy the product on a day when the price happens to be high will likely feel that they are being taken advantage of. To avoid this, most firms try to maintain

²Jean Boivin, Marc P. Giannoni, and Illian Mihov, “Sticky Prices and Monetary Policy: Evidence from Disaggregated U.S. Data,” *American Economic Review*, March 2009, pp. 350–384.

stable prices that do not change very often. Firms do have occasional sales where they lower prices, but on the whole they tend to try to keep prices stable and predictable—the result being price inflexibility.

Another factor that causes sticky prices has to do with the fact that in certain situations, a firm may be afraid that cutting its price may be counterproductive because its rivals might simply match the price cut—a situation often referred to as a “price war.” This possibility is common among firms that only have one or two major rivals. Consider Coca-Cola and Pepsi. If Coca-Cola faces unexpectedly low demand for its product, it might be tempted to reduce its price in the hope that it can steal business away from Pepsi. But such a strategy would only work if Pepsi left its price alone when Coca-Cola cut its price. That, of course, is not likely. If Coca-Cola cuts its price, Pepsi will very likely cut its price in retaliation, doing its best to make sure that Coca-Cola doesn’t steal away any of its customers. Thus, if Pepsi retaliates, Coca-Cola will only be made worse off by its decision to cut its price: It will not pick up much more business (because Pepsi also cut its price) and it will also be receiving less money for each bottle of Coke that it sells (because it lowered its own price.) Thus, firms that have to deal with the possibility of price wars often have sticky prices.

Categorizing Macroeconomic Models Using Price Stickiness

LO26.6 Explain why the greater flexibility of prices as time passes causes economists to utilize different macroeconomic models for different time horizons.

We have now demonstrated why price stickiness is believed to have such a large role in short-run economic fluctuations. It should be noted, however, that price stickiness moderates over time. This is true because firms that choose to use a fixed-price policy in the short run do not have to stick with that policy permanently. In particular, if unexpected changes in demand begin to look permanent, many firms will allow their prices to change so that price changes (in addition to quantity changes) can help to equalize quantities supplied with quantities demanded.

For this reason, economists speak of “sticky prices” rather than “stuck prices.” Only in the very short run are prices totally inflexible. As time passes and prices are revised, the world looks much more like Figure 26.1a, in which prices are fully flexible, than Figure 26.1b, in which prices are totally inflexible. Indeed, the totally inflexible case shown in Figure 26.1b can be thought of as the extremely short-run response to an unexpected change in demand, while the fully flexible case shown in Figure 26.1a can be thought of as a longer-run response to an unexpected change in demand. In terms of time durations, the extreme short run can be thought

of as the first few weeks and months after a demand shock, while the long run can be thought of as extending from many months to several years after a demand shock happens.

This realization is very useful in categorizing and understanding the differences between the various macroeconomic models that we will be presenting in subsequent chapters. For instance, the aggregate expenditures model presented in Chapter 31 assumes perfectly inflexible prices (and wages) and thus is a model in which prices are not just sticky but completely stuck. By contrast, the aggregate demand–aggregate supply model presented in Chapter 32 allows for flexible prices (with or without flexible wages) and is therefore useful for understanding how the economy behaves over longer periods of time.

As you study these various models, keep in mind that we need different models precisely because the economy behaves so differently depending on how much time has passed after a demand shock. The differences in behavior result from the fact that prices go from stuck in the extreme short run to fully flexible in the long run. Using different models for different stages in this process gives us much better insights into not only how economies actually behave but also how various government and central bank policies may have different effects in the short run when prices are fixed versus the long run when prices are flexible.

Where will we go from here? In the remainder of Part 7, we examine how economists measure GDP and why GDP has expanded over time. Then, we discuss the terminology of business cycles and explore the measurement and types of unemployment and inflation. At that point you will be well-prepared to examine the economic models, monetary considerations, and stabilization policies that lie at the heart of macroeconomics.

QUICK REVIEW 26.5

- ✓ Many commodity prices are extremely flexible and change constantly, but other prices in the economy change only very infrequently.
- ✓ Some prices are inflexible in order to please retail customers, others because rival firms are afraid that price changes may trigger a price war.
- ✓ Prices tend to become more flexible over time, so that as time passes, the economy can react to demand shocks with price changes as well as with output and employment changes.
- ✓ Different macroeconomics models are required for the short run, during which prices are inflexible (so that demand shocks lead almost exclusively to output and employment changes), and for longer periods, during which prices become increasingly flexible (so that demand shocks lead more to price changes than output and employment changes).

Debating the Great Recession

Economists Disagreed Vigorously about Both the Causes of the Great Recession and the Best Ways to Speed a Recovery.

The Great Recession of 2007–2009 was the worst economic downturn since the Great Depression of the 1930s. The government intervened massively to help promote recovery, but the recession was long-lasting and the subsequent recovery was the weakest since the Great Depression.

Explanations about what caused the Great Recession differ sharply among economists. Here are two of the more popular hypotheses.

The Minsky Explanation: Euphoric Bubbles Economist Hyman Minsky believed that severe recessions are often preceded by *asset-price bubbles*—periods during which euphoria and debt-fueled speculation cause the price of one or more financial assets to irrationally skyrocket before collapsing down to more realistic levels. Those who apply his ideas to the Great Recession note that easily obtained home-mortgage loans drove a massive bubble in housing prices.

When the bubble eventually collapsed, investors lost trillions of dollars in wealth. As a result, the demand for goods and services fell dramatically and unexpectedly. When combined with sticky prices, that leftward shift in demand forced many companies to reduce output and lay off workers (as in our Buzzer Auto example in this chapter). The weakest firms went bankrupt and had to permanently fire all of their workers.

The Austrian Explanation: Excessively Low Interest Rates Economists of the so-called Austrian School also blame bubbles for severe recessions, but they put the blame for bubbles not on euphoria but on government actions that they say keep interest rates too low. Their contention is that excessively low interest rates induce firms and individuals to borrow excessively. Individuals borrow excessively to fund consumption. Firms borrow excessively for construction and investment. When the bubble pops, society has too many factories (as a result of the massive increase in construction and investment on the part of firms) combined with too little demand (as consumers struggle to repay all the money they borrowed to fund their consumption).

In terms of this chapter's Buzzer Auto example, it would be as though Buzzer borrowed lots of money to build several factories only to discover that demand was much lower than expected because consumers were cutting back on spending in order to repay debt. With demand shifting left and prices sticky, Buzzer and other companies are forced to reduce output and lay off workers. Thus begins the recession.

Because economists did not have a consensus about what caused the Great Recession, it should not be surprising that

they were also divided over the best policies for fighting the recession and improving upon the sluggish recovery that began in 2009. For simplicity, the wide variety of opinions can be grouped into two broad camps promoting two very different solutions.

The Stimulus Solution The majority of economists argued that the solution to the collapse in demand was to have the government take actions to shift demand curves rightward. For instance, the government could lower interest rates so that consumers and businesses would borrow and spend more. The government could also massively increase its purchases of goods and services so that a rightward shift in the government's demand for output could help to make up for the leftward shift in the private-sector demand for output.

This opinion in favor of *government stimulus* was the most commonly held view among economists and the government did in fact push interest rates very low while also massively increasing government spending.

The Structural Solution A vocal minority of economists rejected the stimulus policies. They argued that the economy required a *structural adjustment*. In their opinion, the bubble period before the recession had seen a major misallocation of resources toward inefficient firms that generated net losses for society ($MB < MC$). The only way to redirect the resources that those firms were using back toward productive activities would be to let the inefficient firms go bankrupt. The resources would then flow toward efficient firms whose output generated net benefits for society ($MB > MC$).

Under this way of thinking, government stimulus efforts delayed recovery by keeping many wasteful firms on life support. Those who took that opinion wanted the government to mostly hang back, let inefficient firms go bankrupt, and allow the invisible hand to reallocate resources.

This debate over government stimulus was ongoing and continual during the sluggish recovery from the Great Recession. Those in favor of stimulus argued that the sluggish recovery was the result of too little stimulus. Those against stimulus argued that the sluggish recovery was the result of too much stimulus.

One of your tasks as you work your way through the subsequent chapters will be to understand the nature of this debate and the arguments and evidence on both sides. But don't look for a definitive answer. The complexities of giant national economies are only partly understood and the best policy may have been something unseen by either of the two camps.

SUMMARY

L026.1 Explain why economists focus on GDP, inflation, and unemployment when assessing the health of an entire economy.

Macroeconomics studies long-run economic growth and short-run economic fluctuations.

Macroeconomists focus their attention on three key economic statistics: real GDP, unemployment, and inflation. Real GDP measures the value of all final goods and services produced in a country during a specific period of time. The unemployment rate measures the percentage of all workers who are not able to find paid employment despite being willing and able to work at currently available wages. The inflation rate measures the extent to which the overall level of prices is rising in the economy.

L026.2 Discuss why sustained increases in living standards are a historically recent phenomenon.

Before the Industrial Revolution, living standards did not show any sustained increases over time. Economies grew, but any increase in output tended to be offset by an equally large increase in the population, so that the amount of output per person did not rise. By contrast, since the Industrial Revolution began in the late 1700s, many nations have experienced modern economic growth in which output grows faster than population—so that standards of living rise over time.

L026.3 Identify why saving and investment are key factors in promoting rising living standards.

Macroeconomists believe that one of the keys to modern economic growth is the promotion of saving and investment (for economists, the purchase of capital goods). Investment activities increase the economy's future potential output level. But investment must be funded by saving, which is only possible if people are willing to reduce current consumption. Consequently, individuals and society face a trade-off between current consumption and future consumption since the only way to fund the investment necessary to increase future consumption is by reducing current consumption in order to gather the savings necessary to fund that investment. Banks and other financial institutions help to convert saving into investment by taking the savings generated by households and lending it to businesses that wish to make investments.

L026.4 Describe why economists believe that “shocks” and “sticky prices” are responsible for short-run fluctuations in output and employment.

Expectations have an important effect on the economy for two reasons. First, if people and businesses are more positive about the future, they will save and invest more. Second, individuals and firms

must make adjustments to shocks—situations in which expectations are unmet and the future does not turn out the way people were expecting. In particular, shocks often imply situations where the quantity supplied of a given good or service does not equal the quantity demanded of that good or service.

If prices were always flexible and capable of rapid adjustment, then dealing with situations in which quantities demanded did not equal quantities supplied would always be easy since prices could simply adjust to the market equilibrium price at which quantities demanded equal quantities supplied. Unfortunately, real-world prices are often inflexible (or “sticky”) in the short run so that the only way for the economy to adjust to such situations is through changes in output levels.

Sticky prices combine with shocks to drive short-run fluctuations in output and employment. Consider a negative demand shock in which demand is unexpectedly low. Because prices are fixed, the lower-than-expected demand will result in unexpectedly slow sales. This will cause inventories to increase. If demand remains low for an extended period of time, inventory levels will become too high and firms will have to cut output and lay off workers. Thus, when prices are inflexible, the economy adjusts to unexpectedly low demand through changes in output and employment rather than through changes in prices (which are not possible when prices are inflexible).

L026.5 Characterize the degree to which various prices in the economy are sticky.

Prices are inflexible in the short run for various reasons, two of which are discussed in this chapter. First, firms often attempt to set and maintain stable prices to please customers who like predictable prices because they make for easy planning (and who might become upset if prices were volatile). Second, a firm with just a few competitors may be reluctant to cut its price due to the fear of starting a price war, a situation in which its competitors retaliate by cutting their prices as well—thereby leaving the firm worse off than it was to begin with.

L026.6 Explain why the greater flexibility of prices as time passes causes economists to utilize different macroeconomic models for different time horizons.

Price stickiness moderates over time. As a result, economists have found it sensible to build separate economic models for different time horizons. For instance, some models are designed to reflect the high degree of price inflexibility that occurs in the immediate short run, while other models reflect the high degree of price flexibility that occurs in the long run. The different models allow economists to have a better sense for how various government policies will affect the economy in the short run when prices are inflexible versus the long run when prices are flexible.

- Catalog companies are committed to selling at the prices printed in their catalogs. If a catalog company finds its inventory of sweaters rising, what does that tell you about the demand for sweaters? Was it unexpectedly high, unexpectedly low, or as expected? If the company could change the price of sweaters, would it raise the price, lower the price, or keep the price the same? Given that the company cannot change the price of sweaters, consider the number of sweaters it orders each month from the company that makes its sweaters. If inventories become very high, will the catalog company increase, decrease, or keep orders the same? Given what the catalog company does with its orders, what is likely to happen to employment and output at the sweater manufacturer? **LO26.4**

PROBLEMS

- Suppose that the annual rates of growth of real GDP of Econoland over a five-year period were sequentially as follows: 3 percent, 1 percent, -2 percent, 4 percent, and 5 percent. What was the average of these growth rates in Econoland over these five years? What term would economists use to describe what happened in year 3? Assuming that the price of gold increased by 100 percent over the same period, by what numerical amount did Glitter Gulch's real output change? If the price of gold had not changed, what would have been the change in Glitter Gulch's real output? **L026.1**
- A mathematical approximation called the rule of 70 tells us that the number of years that it will take something that is growing to double in size is approximately equal to the number 70 divided by its percentage rate of growth. Thus, if Mexico's real GDP per person is growing at 7 percent per year, it will take about 10 years ($= 70/7$) to double. Apply the rule of 70 to solve the following problem: Real GDP per person in Mexico in 2005 was about \$11,000 per person, while it was about \$44,000 per person in the United States. If real GDP per person in Mexico grows at the rate of 5 percent per year, about how long will it take Mexico's real GDP per person to reach the level that the United States was at in 2005? (Hint: How many times would Mexico's 2005 real GDP per person have to double to reach the United States' 2005 real GDP per person?) **L026.2**
- Assume that a national restaurant firm called BBQ builds 10 new restaurants at a cost of \$1 million per restaurant. It outfits each restaurant with an additional \$200,000 of equipment and furnishings. To help partially defray the cost of this expansion, BBQ issues and sells 200,000 shares of stock at \$30 per share. What is the amount of economic investment that has resulted from BBQ's actions? How much purely financial investment took place? **L026.3**
- Refer to Figure 26.1b and assume that price is fixed at \$37,000 and that Buzzer Auto needs 5 workers for every 1 automobile produced. If demand is D_M and Buzzer wants to perfectly match its output and sales, how many cars will Buzzer produce and how many workers will it hire? If instead, demand unexpectedly falls from D_M to D_L , how many fewer cars will Buzzer sell? How many fewer workers will it need if it decides to match production to these lower sales? **L026.4**

Measuring Domestic Output and National Income

"Disposable Income Flat." "Personal Consumption Surges." "Investment Spending Stagnates." "GDP Up 4 Percent." These headlines, typical of those found on *Yahoo! Finance* or in *The Wall Street Journal*, give knowledgeable readers

valuable information on the state of the economy. This chapter will help you interpret such headlines and understand the stories reported under them. Specifically, it will help you become familiar with the vocabulary and methods of national income accounting. Such accounting enables economists to measure the long-run rate of economic growth and identify the recessions and expansions associated with the economic ups and downs known as the business cycle. In addition, the terms and ideas that you encounter in this chapter will provide a needed foundation for the macroeconomic models found in subsequent chapters.

Assessing the Economy's Performance

LO27.1 Explain how gross domestic product (GDP) is defined and measured.

National income accounting measures the economy's overall performance. It does for the economy as a whole what private accounting does for the individual firm or for the individual household.

A business firm measures its flows of income and expenditures regularly—usually every 3 months or once a year. With that information in hand, the firm can gauge its economic health. If things are going well and profits are good,

the accounting data can be used to explain that success. Were costs down? Was output up? Have market prices risen? If things are going badly and profits are poor, the firm may be able to identify the reason by studying the record over several accounting periods. All this information helps the firm's managers plot their future strategy.

National income accounting operates in much the same way for the economy as a whole. The Bureau of Economic Analysis (BEA), an agency of the Commerce Department, compiles the National Income and Product Accounts (NIPA) for the U.S. economy. This accounting enables economists and policymakers to:

- Assess the health of the economy by comparing levels of production at regular intervals.
- Track the long-run course of the economy to see whether it has grown, been constant, or declined.
- Formulate policies that will safeguard and improve the economy's health.

Gross Domestic Product

The primary measure of the economy's performance is its annual total output of goods and services or, as it is called, its *aggregate output*. There are several ways to measure aggregate output depending upon how one wishes to define "an economy." For instance, should the value of the cars produced at a Toyota plant in Ohio count as part of the output of the U.S. economy because they are made within the United States or as part of the Japanese economy because Toyota is a Japanese company? As mentioned in Chapter 26, **gross domestic product (GDP)** defines aggregate output as the dollar value of all final goods and services produced within the borders of a country during a specific period of time, typically a year. Under this definition, the value of the cars produced at the Toyota factory in Ohio clearly count as part of U.S. aggregate output rather than Japanese aggregate output because the cars are made within the borders of the United States.¹

A Monetary Measure

By necessity, GDP is a *monetary measure*. To see why, suppose that the economy produces three sofas and two computers in year 1 and two sofas and three computers in year 2. In which year is output greater? We can't answer that question until we attach a price tag to each of the two products to indicate how society evaluates their relative worth.

TABLE 27.1 Comparing Heterogeneous Output by Using Money Prices

Year	Annual Output	Market Value
1	3 sofas and 2 computers	3 at \$500 + 2 at \$2,000 = \$5,500
2	2 sofas and 3 computers	2 at \$500 + 3 at \$2,000 = \$7,000

That's what GDP does. It measures the value of output in monetary terms. Without such a measure we would have no way of comparing the relative values of the vast number of goods and services produced in different years. In Table 27.1 the price of sofas is \$500 and the price of computers is \$2,000. GDP would gauge the output of year 2 (\$7,000) as greater than the output of year 1 (\$5,500) because society places a higher monetary value on the output of year 2. Society is willing to pay \$1,500 more for the combination of goods produced in year 2 than for the combination of goods produced in year 1.

Avoiding Multiple Counting

To measure aggregate output accurately, all goods and services produced in a particular year must be counted once and only once. Because most products go through a series of production stages before they reach the market, some of their components are bought and sold many times. To avoid counting those components each time, GDP includes only the market value of *final goods* and ignores *intermediate goods* altogether.

Intermediate goods are products that are purchased for resale or further processing or manufacturing. **Final goods** are products that are purchased by their end users. Crude oil is an intermediate good; gasoline used for personal transportation is a final good. Steel beams are intermediate goods; completed high-rise apartments are final goods. Lettuce, carrots, and vinegar in restaurant salads are intermediate goods; restaurant salads are final goods. Other examples of final goods are sunglasses bought by consumers, assembly machinery purchased by businesses, surveillance satellites bought by government, and smartphones purchased by foreign buyers.

Why is the value of final goods included in GDP but the value of intermediate goods excluded? Because the value of final goods already includes the value of all the intermediate goods that were used in producing them. Including the value of intermediate goods would amount to **multiple counting**, and that would distort the value of GDP.

To see why, suppose that five stages are needed to manufacture a wool coat and get it to the consumer—the final user. Table 27.2 shows that firm A, a sheep ranch, sells \$120 worth of wool to firm B, a wool processor. Firm A pays out the \$120 in wages, rent, interest, and profit. Firm B processes the wool and sells it to firm C, a coat manufacturer, for \$180. What does firm B do with the \$180 it receives? It pays \$120 to firm A for the wool and uses the remaining \$60 to pay wages, rent, interest, and profit for the resources used in processing the

¹In contrast to GDP, U.S. gross national product (GNP) consists of the total value of all the final goods and services produced by American supplied resources, whether those goods and services are produced within the borders of the United States or abroad. The U.S. switched from GNP to GDP accounting in 1992 to match the type of accounting used by other countries worldwide.

wool. Firm C, the manufacturer, sells the coat to firm D, a wholesaler, which sells it to firm E, a retailer. Then at last a consumer, the final user, comes in and buys the coat for \$350.

How much of these amounts should we include in GDP to account for the production of the coat? Just \$350, the value of the final product. The \$350 includes all the intermediate transactions leading up to the product's final sale. Including the sum of all the intermediate sales, \$1,140, in GDP would amount to multiple counting. The production and sale of the final coat generated just \$350 of output, not \$1,140.

Alternatively, we could avoid multiple counting by measuring and cumulating only the *value added* at each stage. **Value added** is the market value of a firm's output *less* the value of the inputs the firm has bought from others. At each stage, the difference between what a firm pays for inputs and what it receives from selling the product made from those inputs is paid out as wages, rent, interest, and profit. Column 3 of Table 27.2 shows that the value added by firm B is \$60, the difference between the \$180 value of its output and the \$120 it paid for the input from firm A. We find the total value of the coat by adding together all the values added by the five firms. Similarly, by calculating and summing the values added to all the goods and services produced by all firms in the economy, we can find the market value of the economy's total output—its GDP.

GDP Excludes Nonproduction Transactions

Although many monetary transactions in the economy involve final goods and services, many others do not. These nonproduction transactions must be excluded from GDP because they have nothing to do with the generation of final goods. *Nonproduction transactions* are of two types: purely financial transactions and secondhand sales.

Financial Transactions Purely financial transactions include the following:

- **Public transfer payments** These are the social security payments, welfare payments, and veterans' payments

that the government makes directly to households. Since the recipients contribute nothing to *current production* in return, to include such payments in GDP would be to overstate the year's output.

- **Private transfer payments** Such payments include, for example, the money that parents give children or the cash gifts given during the holidays. They produce no output. They simply transfer funds from one private individual to another and consequently do not enter into GDP.
- **Stock market transactions** The buying and selling of stocks (and bonds) is just a matter of swapping bits of paper. Stock market transactions create nothing in the way of current production and are not included in GDP. Payments for the services provided by a stockbroker *are* included, however, because their services are currently provided and are thus a part of the economy's current output of goods and services.

Secondhand Sales Secondhand sales contribute nothing to current production and for that reason are excluded from GDP. Suppose you sell your 2010 Ford Mustang to a friend; that transaction would be ignored in reckoning this year's GDP because it generates no current production. The same would be true if you sold a brand-new Mustang to a neighbor a week after you purchased it.

Two Ways of Looking at GDP: Spending and Income

Let's look again at how the market value of total output—or of any single unit of total output—is measured. Given the data listed in Table 27.2, how can we measure the market value of a coat?

One way is to see how much the final user paid for it. That will tell us the market value of the final product. Or we can add up the entire wage, rental, interest, and profit incomes that were created in producing the coat. The second approach is the value-added technique used in Table 27.2.

FIGURE 27.1 The expenditures and income approaches to GDP. There are two general approaches to measuring gross domestic product. We can determine GDP as the value of output by summing all expenditures on that output. Alternatively, with some modifications, we can determine GDP by adding up all the components of income arising from the production of that output.

Income, or allocations, approach

The final-product approach and the value-added approach are two ways of looking at the same thing. What is spent on making a product is income to those who helped make it. If \$350 is spent on manufacturing a coat, then \$350 is the total income derived from its production.

We can look at GDP in the same two ways. We can view GDP as the sum of all the money spent in buying it. That is the *output approach*, or **expenditures approach**. Or we can view GDP in terms of the income derived or created from producing it. That is the *earnings or allocations approach*, or the **income approach**.

As illustrated in Figure 27.1, we can determine GDP for a particular year either by adding up all that was spent to buy total output or by adding up all the money that was derived as income from its production. Buying (spending money) and selling (receiving income) are two aspects of the same transaction. On the expenditures side of GDP, all final goods produced by the economy are bought either by three domestic sectors (households, businesses, and government) or by foreign buyers. On the income side (once certain statistical adjustments are made), the total receipts acquired from the sale of that total output are allocated to the suppliers of resources as wage, rent, interest, and profit.

Table 27.3 shows U.S. GDP for the year 2015 totaled up using the expenditures approach while Table 27.4 shows U.S. GDP for 2015 totaled up using the income approach. As you would expect, both methods reach the same conclusion: U.S. GDP in 2015 was \$17,947 billion.

We will now go through both approaches in detail. Doing so will help you better understand both methods and, in particular, why the income accounting statement shown in Table 27.4 looks substantially more complicated than the income side of Figure 27.1.

The Expenditures Approach

L027.2 Describe how expenditures on goods and services can be summed to determine GDP.

To determine GDP using the expenditures approach, we add up all the spending on final goods and services that has taken

place throughout the year. National-income accountants use precise terms for the types of spending listed on the left side of Figure 27.1.

Personal Consumption Expenditures (C)

What we have called “consumption expenditures by households,” the national income accountants call **personal consumption expenditures**. This term covers all expenditures by households on goods and services.

In a typical year, roughly 10 percent of these personal consumption expenditures are on **durable goods**—products that have expected lives of 3 years or more. Such goods include new automobiles, furniture, and refrigerators. Another 30 percent are on **nondurable goods**—products with less than 3 years of expected life. Included are goods like food, clothing, and gasoline. About 60 percent of personal consumption expenditures are on **services**—the work done by lawyers, hair stylists, doctors, mechanics, and other service providers. Because of this high percentage, economists sometimes refer to the U.S. economy as a *service economy*. National income accountants combine the household spending on durable goods, nondurable goods, and services and use the symbol C to designate the personal consumption expenditures component of GDP.

Gross Private Domestic Investment (I_g)

Under the heading **gross private domestic investment**, the accountants include the following items:

- All final purchases of machinery, equipment, and tools by business enterprises.
- All construction.
- Changes in inventories.
- Money spent on research and development (R&D) or for the creation of new works of art, music, writing, film, and so on.

Notice that this list, except for the first item, includes more than we have meant by “investment” so far. The second item

includes residential construction as well as the construction of new factories, warehouses, and stores. Why do the accountants regard residential construction as investment rather than consumption? Because apartment buildings and houses, like factories and stores, earn income when they are rented or leased. Owner-occupied houses are treated as investment goods because they *could be* rented to bring in an income return. So the national income accountants treat all residential construction as investment.

Increases in inventories (unsold goods) are considered to be investment because they represent, in effect, “unconsumed output.” For economists, all new output that is not consumed is, by definition, capital. An increase in inventories is an addition (although perhaps temporary) to the stock of capital goods, and such additions are precisely how we define investment.

Starting in 2013, the NIPA accountants who compile U.S. GDP statistics began to include expenditures on R&D as well as money spent to develop new works of writing, art, music, and software as a form of investment. They did so because a country’s stock of “capital goods” useful in producing output can be thought of as including not only tangible pieces of physical capital like fiber optic networks and factories but also useful ideas that increase the economy’s ability to produce goods and services.

Software is a great example, as it is merely sets of instructions for telling computers what to do. But without those instructions, computers would be useless. So spending on software as well as on R&D and other intellectual activities that improve the economy’s stock of “know-how” are now counted as investment.

To make it possible to compare GDP numbers across time, the accountants have gone back and applied the new, more comprehensive definition of investment all the way back to 1929. The numbers for U.S. GDP for the year 2015 that are used in this chapter incorporate the revised definition of investment.

Positive and Negative Changes in Inventories We need to look at changes in inventories more closely. Inventories can either increase or decrease over some period. Suppose they increased by \$10 billion between December 31, 2015, and December 31, 2016. Therefore, in 2016 the economy produced \$10 billion more output than people purchased. We need to count all output produced in 2016 as part of that year’s GDP, even though some of it remained unsold at the end of the year. This is accomplished by including the \$10 billion increase in inventories as investment in 2016. That way the expenditures in 2016 will correctly measure the output produced that year.

Alternatively, suppose that inventories decreased by \$10 billion in 2016. This “drawing down of inventories” means that the economy sold \$10 billion more of output in 2016 than it produced that year. It did this by selling goods produced in prior years—goods already counted as GDP in those years. Unless corrected, expenditures in 2016 will overstate GDP for 2016. So in 2016 we consider the \$10 billion decline in inventories as “negative investment” and subtract it from total investment that year. Thus, expenditures in 2016 will correctly measure the output produced in 2016.

Noninvestment Transactions So much for what investment *is*. You also need to know what it *isn't*. For economists and NIPA accountants, investment does *not* include noninvestment transactions such as the transfer of paper assets (stocks, bonds) or the resale of tangible assets (houses, jewelry, boats). Such financial transactions merely transfer the ownership of existing assets. The investment in the GDP accounts is economic investment—the creation of *new* capital assets. The mere transfer (sale) of claims to existing capital goods does not produce new capital goods. Therefore such transactions (so-called financial investments) are not included as investment in the GDP accounts.

Gross Investment versus Net Investment As we have seen, the category gross private domestic investment includes (1) all final purchases of machinery, equipment, and tools; (2) all construction; (3) changes in inventories; and (4) spending on R&D and other activities that expand the economy's stock of technology and know-how. The words “private” and “domestic” mean that we are speaking of spending by private businesses, not by government (public) agencies, and that the investment is taking place inside the country, not abroad.

The word “gross” means that we are referring to *all* investment goods—both those that replace machinery, equipment, and buildings that were used up (worn out or made obsolete) in producing the current year's output and any net additions to the economy's stock of capital. Gross investment includes investment in replacement capital *and* in added capital.

In contrast, **net private domestic investment** includes *only* investment in the form of added capital. The amount of capital that is used up over the course of a year is called *depreciation*. So

$$\text{Net investment} = \text{gross investment} - \text{depreciation}$$

In typical years, gross investment exceeds depreciation. Thus net investment is positive and the nation's stock of capital rises by the amount of net investment. As illustrated in Figure 27.2, the stock of capital at the end of the year exceeds the stock of capital at the beginning of the year by the amount of net investment.

Gross investment need not always exceed depreciation, however. When gross investment and depreciation *are equal*, net investment is zero and there is no change in the size of the capital stock. When gross investment *is less than*

depreciation, net investment is negative. The economy then is *disinvesting*—using up more capital than it is producing—and the nation's stock of capital shrinks. That happened in the Great Depression of the 1930s.

National income accountants use the symbol I for private domestic investment spending. To differentiate between gross investment and net investment, they add either the subscript g or the subscript n . But it is gross investment, I_g , that they use when tallying up GDP.

Government Purchases (G)

The third category of expenditures in the national income accounts is **government purchases**, officially labeled “government consumption expenditures and gross investment.” These expenditures have three components: (1) expenditures for goods and services that government consumes in providing public services; (2) expenditures for *publicly owned capital* such as schools and highways, which have long lifetimes; and (3) government expenditures on R&D and other activities that increase the economy's stock of know-how. Government purchases (federal, state, and local) include all government expenditures on final goods and all direct purchases of resources, including labor. It does *not* include government transfer payments because, as we have seen, they merely transfer government receipts to certain households and generate no production of any sort. National income accountants use the symbol G to signify government purchases.

Net Exports (X_n)

International trade transactions are a significant item in national income accounting. But when calculating U.S. GDP, we must keep in mind that we want to total up only those expenditures that are used to purchase goods and services produced *within the borders of the United States*. Thus, we must add in the value of exports, X , since exports are by definition goods and services produced within the borders of the United States. Don't be confused by the fact that the expenditures made to buy our exports are made by foreigners. The definition of GDP does not care about *who* is making expenditures on U.S.-made goods and services—only that the goods and services that they buy are made within the borders of the United States. Thus, foreign spending on our exports *must* be included in GDP.

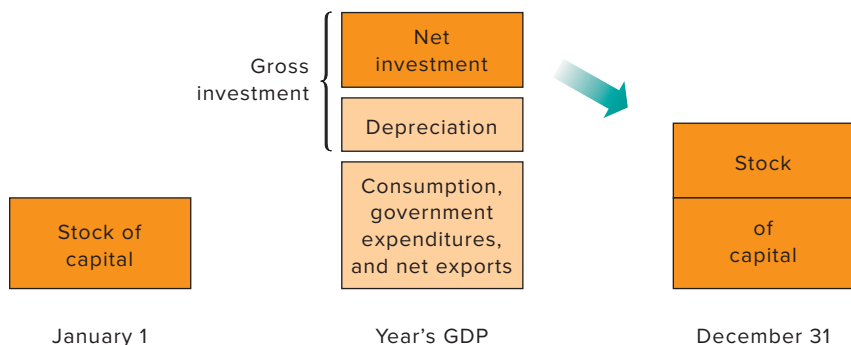

FIGURE 27.2 Gross investment, depreciation, net investment, and the stock of capital. When gross investment exceeds depreciation during a year, net investment occurs. This net investment expands the stock of private capital from the beginning of the year to the end of the year by the amount of the net investment. Other things equal, the economy's production capacity expands.

Stocks versus Flows

An analogy of a reservoir is helpful in thinking about a nation's capital stock, investment, and depreciation. Picture a reservoir that has water flowing in from a river and flowing out from an outlet after it passes through turbines. The volume of water in the reservoir *at any particular point in time* is a "stock." In contrast, the inflow from the river and outflow from the outlet are "flows."

The volume or stock of water in the reservoir will rise if the weekly inflow exceeds the weekly outflow. It will fall if the inflow is less than the outflow. And it will remain constant if the two flows are equal.

Now let's apply this analogy to the stock of capital, gross investment, and depreciation. The stock of capital is the total capital in place at any point in time and is analogous to the level of water in the reservoir. Changes in this capital stock over some period, for example, 1 year, depend on *gross investment* and *depreciation*. Gross investment (analogous to the reservoir inflow) is an addition of capital goods and therefore adds to the stock of capital, while depreciation (analogous to the reservoir outflow) is the using up of capital and thus subtracts from the capital stock. The capital stock increases when gross investment exceeds depreciation, declines when gross investment is less than depreciation, and remains the same when gross investment and depreciation are equal.

Alternatively, the stock of capital increases when *net investment* (gross investment *minus* depreciation) is positive. When net investment is negative, the stock of capital declines, and when net investment is zero, the stock of capital remains constant.

At this point, you might incorrectly think that GDP should be equal to the sum of $C + I_g + G + X$. But this sum overstates GDP. The problem is that, once again, we must consider only expenditures made on *domestically produced* goods and services. As it stands, C , I_g , and G count expenditures on consumption, investment, and government purchases *regardless* of where those goods and services are made. Crucially, not all of the C , I_g , or G expenditures are for domestically produced goods and services. Some of the expenditures are for imports—goods and services produced outside of the United States. Because we wish to count *only* the part of C , I_g , and G that goes to purchasing domestically produced goods and services, we must subtract the spending that goes to imports, M . That subtraction yields the correct formula for calculating gross domestic product: $GDP = C + I_g + G + X - M$.

GLOBAL PERSPECTIVE 27.1

Comparative GDPs in Trillions of U.S. Dollars, Selected Nations, 2014

The United States, China, and Japan have the world's highest GDPs. The GDP data charted below have been converted to U.S. dollars via international exchange rates.

Accountants simplify this formula for GDP by defining **net exports**, X_n , to be equal to exports minus imports:

$$\text{Net exports } (X_n) = \text{exports } (X) - \text{imports } (M)$$

Using this definition of net exports, the formula for gross domestic product simplifies to,

$$GDP = C + I_g + G + X_n$$

Table 27.3 shows that in 2015 Americans spent \$529 billion more on imports than foreigners spent on U.S. exports. That is, net exports in 2015 were a *minus* \$529 billion.

Putting It All Together:

$$GDP = C + I_g + G + X_n$$

Taken together, the four categories of expenditures provide a measure of the market value of a specific year's total output—its GDP. Table 27.3 indicates that 2015 U.S. GDP (in billions) totaled:

$$GDP = \$12,272 + \$3,021 + \$3,183 - \$529$$

Global Perspective 27.1 lists the GDPs of several countries. The values of GDP are converted to dollars using international exchange rates.

The Income Approach

L027.3 Explain how GDP can be determined by summing up all of the incomes that were derived from producing the economy's output of goods and services.

Table 27.4 shows how 2015's expenditures of \$17,947 billion were allocated as income to those responsible for producing the output. It would be simple if we could say that the entire amount of expenditures flowed back to them in the form of wages, rent, interest, and profit. But some expenditures flow to other recipients (such as the government) or to other uses (such as paying to replace the capital goods that have worn out while producing this year's GDP). These must be accounted for to balance the expenditures and income sides of the overall account. We will begin by looking at the items that make up *national income*.

Compensation of Employees

By far the largest share of national income—\$9,655 billion in 2015—was paid as wages and salaries by business and government to their employees. That figure also includes wage and salary supplements, in particular, payments by employers into social insurance and into a variety of private pension, health, and welfare funds for workers.

Rents

Rents consist of the income received by the households and businesses that supply property resources. They include the monthly payments tenants make to landlords and the lease payments corporations pay for the use of office space. The figure used in the national accounts is *net* rent—gross rental income minus depreciation of the rental property.

Interest

Interest consists of the money paid by private businesses to the suppliers of loans used to purchase capital. It also includes such items as the interest households receive on savings deposits, certificates of deposit (CDs), and corporate bonds.

Proprietors' Income

What we have loosely termed “profits” is broken down by the national income accountants into two accounts: proprietors' income, which consists of the net income of sole proprietorships, partnerships, and other unincorporated businesses; and corporate profits. Proprietors' income flows to the proprietors.

Corporate Profits

Corporate profits are the earnings of corporations. National income accountants subdivide corporate profits into three categories:

- **Corporate income taxes** These taxes are levied on corporations' profits. They flow to the government.
- **Dividends** These are the part of after-tax profits that corporations choose to pay out, or distribute, to their stockholders. They thus flow to households—the ultimate owners of all corporations.
- **Undistributed corporate profits** Any after-tax profits that are not distributed to shareholders are saved, or retained, by corporations to be invested later in new plants and equipment. Undistributed corporate profits are also called *retained earnings*.

Taxes on Production and Imports

The account called **taxes on production and imports** includes general sales taxes, excise taxes, business property taxes, license fees, and customs duties. Why do national income accountants add these indirect business taxes to wages, rent, interest, and profits in determining national income? The answer is, “to account for expenditures that are diverted to the government.” Consider an item that would otherwise sell for \$1 but costs \$1.05 because the government has imposed a 5 percent sales tax. When this item is purchased, consumers will expend \$1.05 to buy it. But only \$1 will go to the seller (who will then distribute it as income in the form of wages, rent, interest, and profit in order to compensate resource providers). The remaining 5 cents will flow as revenue to the government. The GDP accountants handle the extra 5 cents by placing it into the category called “Taxes on Production and Imports” and loosely consider it to be “income” to government.

From National Income to GDP

We have just shown that expenditures on final goods and services flow either as income to private citizens or as “income” to government. As a result, **national income** is the total of all sources of private income (employee compensation, rents, interest, proprietors' income, and corporate profits) plus government revenue from taxes on production and imports. National income is all the income that flows to American-supplied resources, whether here or abroad, plus taxes on production and imports. But notice that the figure for national income shown in Table 27.4—\$15,535 billion—is less than GDP as reckoned by the expenditures approach shown in Table 27.3. The two versions of the accounting statement—the expenditures version and the income version—are brought into balance by subtracting one item from national income and adding two others.

Net Foreign Factor Income First, we need to make a slight adjustment in “national” income versus “domestic” income. National income includes the total income of

Americans, whether it was earned in the United States or abroad. But GDP is a measure of *domestic* output—total output produced within the United States regardless of the nationality of those who provide the resources. So in moving from national income to GDP, we must take out the income Americans gain from supplying resources abroad and add in the income that foreigners gain by supplying resources in the United States. That process provides *net foreign factor income*. In 2015, net foreign factor income was \$214 billion, meaning that American-owned resources earned \$214 billion more in other countries than foreign-owned resources earned in the United States. Because this \$214 billion is earnings of Americans, it is included in U.S. national income. But this income is not part of U.S. domestic income because it reflects earnings from output produced in other nations. It is part of those nations' domestic income, derived from production of their domestic output. Thus, we subtract net foreign factor income from U.S. national income to stay on the correct path to use the income approach to determine the value of *U.S. domestic output* (output produced within U.S. borders).

Consumption of Fixed Capital Next, we must recognize that the useful lives of private capital equipment (such as bakery ovens or automobile assembly lines) extend far beyond the year in which they were produced. To avoid understating profit and income in the year of purchase and to avoid overstating profit and income in succeeding years, the cost of such capital must be allocated over its lifetime. The amount allocated is an estimate of how much of the capital is being used up each year. It is called *depreciation*. Accounting for depreciation results in a more accurate statement of profit and income for the economy each year. Publicly owned capital, such as courthouses and bridges, also requires a depreciation allowance in the national income accounts.

The huge depreciation charge made against private and publicly owned capital each year is called **consumption of fixed capital** because it is the allowance for capital that has been “consumed” in producing the year's GDP. It is the portion of GDP that is set aside to pay for the ultimate replacement of those capital goods.

The money allocated to consumption of fixed capital (the depreciation allowance) is a cost of production and thus included in the gross value of output. But this money is not available for other purposes, and, unlike other costs of production, it does not add to anyone's income. So it is not included in national income. We must therefore add it to national income to achieve balance with the economy's expenditures.

Statistical Discrepancy As you know, it should be possible to calculate GDP either by totaling up expenditures or by summing up incomes. Either method should give the same result.

In practice, however, it is not possible for NIPA accountants to measure every input into either set of calculations with total precision. Difficulties arise due to a wide range of factors including people misreporting their incomes on tax returns and the difficulty involved with accurately estimating depreciation. As a result, the GDP number produced by the income method always differs by a small percentage from the GDP number produced by the expenditures method.

To account for this difference, NIPA accountants add a statistical discrepancy to national income. The addition of that number equalizes the GDP totals produced by the two methods. In 2015 the discrepancy value was negative \$195 billion, or about 1 percent of GDP.

Table 27.3 summarizes the expenditures approach to GDP while Table 27.4 summarizes the income approach to GDP. Table 27.3 shows how much the U.S. economy produced in 2015 by showing how much was spent to purchase that year's output of goods and services. Table 27.4 shows how those expenditures were allocated either as income to individuals, as revenue to the government, or to other uses such as paying for the replacement of depreciated capital.

QUICK REVIEW 27.1

- ✓ Gross domestic product (GDP) is a measure of the total market value of all final goods and services produced by the economy in a specific year.
- ✓ The expenditures approach to GDP sums the total spending on final goods and services: $GDP = C + I_g + G + X_n$.
- ✓ The economy's stock of private capital expands when net investment is positive; stays constant when net investment is zero; and declines when net investment is negative.
- ✓ The income approach to GDP sums compensation to employees, rent, interest, proprietors' income, corporate profits, and taxes on production and imports to obtain national income, and then subtracts net foreign factor income and adds consumption of fixed capital and a statistical discrepancy to obtain GDP.

Other National Accounts

LO27.4 Describe the relationships among GDP, net domestic product, national income, personal income, and disposable income.

Several other national accounts provide additional useful information about the economy's performance. We can derive these accounts by making various adjustments to GDP.

Net Domestic Product

As a measure of total output, GDP does not make allowances for replacing the capital goods used up in each year's production. As a result, it does not tell us how much new output was available for consumption and for additions to the stock of capital. To determine that, we must subtract from GDP the capital that was consumed in producing the GDP and that had to be replaced. That is, we need to subtract consumption of fixed capital (depreciation) from GDP. The result is a measure of **net domestic product (NDP)**:

$$\text{NDP} = \text{GDP} - \text{consumption of fixed capital (depreciation)}$$

For the United States in 2015:

	Billions
Gross domestic product	\$17,947
Less: Consumption of fixed capital	2,821
<i>Equals:</i> Net domestic product	\$15,126

NDP is simply GDP adjusted for depreciation. It measures the total annual output that the entire economy—households, businesses, government, and foreigners—can consume without impairing its capacity to produce in ensuing years.

National Income

Sometimes it is useful to know how much Americans earned for their contributions of land, labor, capital, and entrepreneurial talent. Recall that U.S. national income (NI) includes all income earned through the use of American-owned resources, whether they are located at home or abroad. It also includes taxes on production and imports. To derive NI from NDP, we must subtract the aforementioned statistical discrepancy from NDP and add net foreign factor income, since the latter is income earned by Americans overseas minus income earned by foreigners in the United States.

For the United States in 2015:

	Billions
Net domestic product	\$15,126
Less: Statistical discrepancy	-195
Plus: Net foreign factor income	214
<i>Equals:</i> National income	\$15,535

We know, too, that we can calculate national income through the income approach by simply adding up employee compensation, rent, interest, proprietors' income, corporate profit, and taxes on production and imports.

Personal Income

Personal income (PI) includes all income received, whether earned or unearned. It is likely to differ from national income

(income earned) because some income earned—taxes on production and imports, Social Security taxes (payroll taxes), corporate income taxes, and undistributed corporate profits—is not received by households. Conversely, some income received—such as Social Security payments, unemployment compensation payments, welfare payments, disability and education payments to veterans, and private pension payments—is not earned. These transfer payments must be added to obtain PI.

In moving from national income to personal income, we must subtract the income that is earned but not received and add the income that is received but not earned. For the United States in 2015:

	Billions
National income	\$15,535
Less: Taxes on production and imports	1,177
Less: Social Security contributions	1,203
Less: Corporate income taxes	530
Less: Undistributed corporate profits	591
Plus: Transfer payments	3,306*
<i>Equals:</i> Personal income	\$15,340

*Includes statistical discrepancy and rounding error.

Disposable Income

Disposable income (DI) is personal income less personal taxes. Personal taxes include personal income taxes, personal property taxes, and inheritance taxes. Disposable income is the amount of income that households have left over after paying their personal taxes. They are free to divide that income between consumption (C) and saving (S):

$$\text{DI} = C + S$$

For the United States in 2015:

	Billions
Personal income	\$15,340
Less: Personal taxes	1,945
<i>Equals:</i> Disposable income	\$13,395

Table 27.5 summarizes the relationships among GDP, NDP, NI, PI, and DI.

the allocations of GDP and then the adjustments needed to derive NDP, NI, PI, and DI.

The diagram illustrates the adjustments necessary to determine each of the national income accounts. For example, net domestic product is smaller than GDP because consumption of fixed capital flows away from GDP in determining NDP. Also, disposable income is smaller than personal income because personal taxes flow away from PI (to government) in deriving DI.

Note the three domestic sectors of the economy: households, government, and businesses. The household sector has an inflow of disposable income and outflows of consumption spending and savings. The government sector has an inflow of revenue in the form of types of taxes and an outflow of government disbursements in the form of purchases and transfers. The business sector has inflows from three major sources of funds for business investment and an outflow of investment expenditures.

Also, take a look at the foreign sector (all other countries) in the flow diagram. Spending by foreigners on U.S. exports adds to U.S. GDP, but some of U.S. consumption, government, and investment expenditures buys imported products. The flow from foreign markets shows that we handle this complication by calculating net exports (U.S. exports minus U.S. imports). The net export flow may be a positive or negative amount, adding to or subtracting from U.S. GDP.

Finally, you need to be aware that the flows shown in Figure 27.3 are dynamic entities and generally expand in size over time as the economy grows. But not always! Case in point: The Great Recession of 2007–2009—which is described in a Consider This box in Chapter 26—produced a pronounced slowing of the main spending and income flows. Specifically, U.S. businesses greatly reduced investment expenditures and households initially reduced personal consumption expenditures. Consequently, GDP, NDP, NI, and PI all significantly declined.

QUICK REVIEW 27.2

- ✓ Net domestic product (NDP) is the market value of GDP minus consumption of fixed capital (depreciation).
- ✓ National income (NI) is all income earned through the use of American-owned resources, whether located at home or abroad. NI also includes taxes on production and imports.
- ✓ Personal income (PI) is all income received by households, whether earned or not.
- ✓ Disposable income (DI) is all income received by households minus personal taxes.

Nominal GDP versus Real GDP

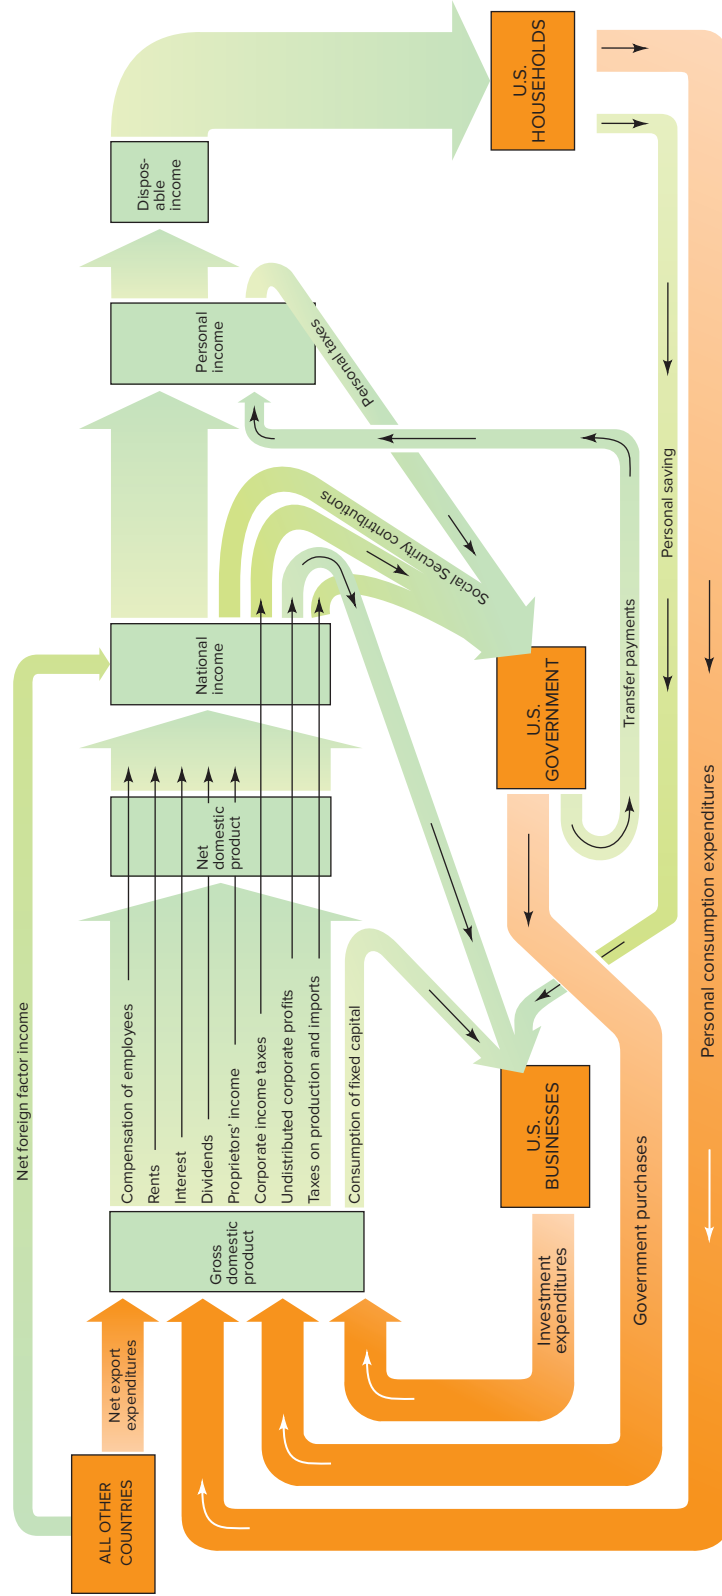

LO27.5 Discuss the nature and function of a GDP price index, and describe the difference between nominal GDP and real GDP.

Recall that GDP is a measure of the market or money value of all final goods and services produced by the economy in a given year. We use money or nominal values as a common denominator to sum that heterogeneous output into a meaningful total. But, as alluded to in Chapter 26, that creates a problem: How can we compare the market values of GDP from year to year if the value of money itself changes in response to inflation (rising prices) or deflation (falling prices)? After all, we determine the value of GDP by multiplying total output by market prices.

Whether there is a 5 percent increase in output with no change in prices or a 5 percent increase in prices with no change in output, the change in the value of GDP will be the same. And yet it is the *quantity* of goods and services that get produced and distributed to households that affects our standard of living, not the price of those goods and services. For instance, the McDonald's hamburger that sold for \$1.29 in 2015 yields the same satisfaction as a nearly identical McDonald's hamburger that sold for 18 cents in 1967.

The way around this problem is to *deflate* GDP when prices rise and to *inflate* GDP when prices fall. These adjustments give us a measure of GDP for various years as if the value of the dollar had always been the same as it was in

FIGURE 27.3 U.S. domestic output and the flows of expenditure and income. This figure is an elaborate circular flow diagram that fits the expenditures and allocations sides of GDP to one another. The expenditures flows are shown in orange; the allocations or income flows are shown in green. You should trace through the income and expenditures flows, relating them to the five basic national income accounting measures.

some reference year. A GDP based on the prices that prevailed when the output was produced is called unadjusted GDP, or **nominal GDP**. A GDP that has been deflated or inflated to reflect changes in the price level is called adjusted GDP, or **real GDP**.

Adjustment Process in a One-Product Economy

There are two ways we can adjust nominal GDP to reflect price changes. For simplicity, let's assume that the economy produces only one good, pizza, in the amounts indicated in Table 27.6 for years 1, 2, and 3. Suppose that we gather revenue data directly from the financial reports of the economy's pizza businesses to measure nominal GDP in various years. After completing our effort, we will have determined nominal GDP for each year, as shown in column 4 of Table 27.6. We will have no way of knowing to what extent changes in price and/or changes in quantity of output have accounted for the increases or decreases in nominal GDP that we observe.

GDP Price Index How can we determine real GDP in our pizza economy? One way is to assemble data on the price changes that occurred over various years (column 2) and use them to establish an overall price index for the entire period. Then we can use the index in each year to adjust nominal GDP to real GDP for that year.

In the actual economy, a **price index** is a measure of the price of a specified collection of goods and services, called a "market basket," in a given year as compared to the price of an identical (or highly similar) collection of goods and services in a reference year. That point of reference, or benchmark, is known as the base period, **base year**, or, simply, the reference year. More formally,

$$\text{Price index in given year} = \frac{\text{price of market basket in specific year}}{\text{price of same market basket in base year}} \times 100 \quad (1)$$

By convention, the price ratio between a given year and the base year is multiplied by 100 to facilitate computation. For example, a price ratio of 2/1 (= 2) is expressed as a price index of 200. A price ratio of 1/3 (= 0.33) is expressed as a price index of 33.

In our pizza-only example, of course, our market basket consists of only one product. Column 2 of Table 27.6 reveals that the price of pizza was \$10 in year 1, \$20 in year 2, \$25 in year 3, and so on. Let's select year 1 as our base year. Now we can express the successive prices of the contents of our market basket in, say, years 2 and 3 as compared to the price of the market basket in year 1:

$$\text{Price index, year 2} = \frac{\$20}{\$10} \times 100 = 200$$

$$\text{Price index, year 3} = \frac{\$25}{\$10} \times 100 = 250$$

For year 1 the index has to be 100, since that year and the base year are identical.

The index numbers tell us that the price of pizza rose from year 1 to year 2 by 100 percent (= [(200 - 100)/100] × 100) and from year 1 to year 3 by 150 percent (= [(250 - 100)/100] × 100).

Dividing Nominal GDP by the Price Index We can now use the index numbers shown in column 3 to deflate the nominal GDP figures in column 4. The simplest and most direct method of deflating is to express the index numbers as hundredths—in decimal form—and then to divide them into corresponding nominal GDP. That gives us real GDP:

$$\text{Real GDP} = \frac{\text{nominal GDP}}{\text{price index (in hundredths)}} \quad (2)$$

Column 5 shows the results. These figures for real GDP measure the market value of the output of pizza in years 1, 2, and 3 as if the price of pizza had been a constant \$10 throughout the 3-year period. In short, real GDP reveals the market value of each year's output measured in terms of dollars that have the same purchasing power as dollars had in the base year.

TABLE 27.6 Calculating Real GDP (Base Year = Year 1)

Year	(1) Units of Output	(2) Price of Pizza per Unit	(3) Price Index (Year 1 = 100)	(4) Unadjusted, or Nominal, GDP, (1) × (2)	(5) Adjusted, or Real, GDP
1	5	\$10	100	\$ 50	\$50
2	7	20	200	140	70
3	8	25	250	200	80
4	10	30	—	—	—
5	11	28	—	—	—

To test your understanding, extend Table 27.6 to years 4 and 5, using equations 1 and 2. Then run through the entire deflating procedure, using year 3 as the base period. This time you will have to inflate some of the nominal GDP data, using the same procedure as we used in the examples.

An Alternative Method

Another way to calculate real GDP is to gather separate data on physical outputs (as in column 1) and their prices (as in column 2) of Table 27.6. We could then determine the market value of outputs in successive years *if the base-year price (\$10) had prevailed*. In year 2, the 7 units of pizza would have a value of \$70 (= 7 units × \$10). As column 5 confirms, that \$70 worth of output is year 2's real GDP. Similarly, we could determine the real GDP for year 3 by multiplying the 8 units of output that year by the \$10 price in the base year.

Once we have determined real GDP through this method, we can identify the price index for a given year simply by dividing the nominal GDP by the real GDP for that year:

$$\text{Price index (in hundredths)} = \frac{\text{nominal GDP}}{\text{real GDP}} \quad (3)$$

Example: In year 2 we get a price index of 200—or, in hundredths, 2.00—which equals the nominal GDP of \$140 divided by the real GDP of \$70. Note that equation 3 is simply a rearrangement of equation 2. Table 27.7 summarizes the two methods of determining real GDP in our single-good economy.

Real-World Considerations and Data

In the real world of many goods and services, of course, determining GDP and constructing a reliable price index are far more complex matters than in our pizza-only economy. The government accountants must assign a “weight” to each of several categories of goods and services based on the

relative proportion of each category in total output. They update the weights annually as expenditure patterns change and roll the base year forward year by year using a moving average of expenditure patterns. The GDP price index used in the United States is called the *chain-type annual-weights price index*—which hints at its complexity. We spare you the details.

Table 27.8 shows some of the relationships among nominal GDP, real GDP, and the GDP price index for the U.S. economy. Here the base year is 2009, where the value of the index is set at 100. Because the U.S. price level has been rising over the long run, the pre-2009 values of real GDP (column 3) are higher than the nominal values of GDP for those years (column 2). This upward adjustment acknowledges that prices were lower in the years before 2009, and thus nominal GDP understated the real output of those years in 2009 prices and must be inflated to show the correct relationship to other years.

Conversely, the rising price level of the post-2009 years caused nominal GDP figures for those years to overstate real output. So the statisticians deflate those figures to determine what real GDP would have been in other years if 2009 prices had prevailed. Doing so reveals that real GDP has been less than nominal GDP since 2009.

By inflating the nominal pre-2009 GDP data and deflating the post-2009 data, government accountants determine annual real GDP, which can then be compared with the real GDP of any other year in the series of years. So the real GDP values in column 3 are directly comparable with one another.

Once we have determined nominal GDP and real GDP, we can compute the price index. And once we have determined nominal GDP and the price index, we can calculate real GDP. Example: Nominal GDP in 2015 was \$17,947.0

TABLE 27.7 Steps for Deriving Real GDP from Nominal GDP

Method 1
1. Find nominal GDP for each year.
2. Compute a GDP price index.
3. Divide each year's nominal GDP by that year's price index (in hundredths) to determine real GDP.
Method 2
1. Break down nominal GDP into physical quantities of output and prices for each year.
2. Find real GDP for each year by determining the dollar amount that each year's physical output would have sold for if base-year prices had prevailed. (The GDP price index can then be found by dividing nominal GDP by real GDP.)

billion and real GDP was \$16,348.9 billion. So the price level in 2015 was 109.8 ($= [\$17,947.0/\$16,348.9] \times 100$), or 9.8 percent higher than in 2009. If we knew the nominal GDP and the price level only, we could find the real GDP for 2015 by dividing the nominal GDP of \$17,947.0 by the 2015 price index, expressed in hundredths (1.098).

To test your understanding of the relationships between nominal GDP, real GDP, and the price level, determine the values of the price index for 1995 in Table 27.8 and determine real GDP for 2000 and 2009. We have left those figures out on purpose.

QUICK REVIEW 27.3

- ✓ Nominal GDP is output valued at current prices. Real GDP is output valued at constant base-year prices.
- ✓ The GDP price index compares the price (market value) of all the goods and services included in GDP in a given year to the price of the same market basket in a reference year.
- ✓ Nominal GDP can be transformed into real GDP by dividing the nominal GDP by the GDP price index expressed in hundredths.

Shortcomings of GDP

LO27.6 List and explain some limitations of the GDP measure. GDP is a reasonably accurate and highly useful measure of how well or how poorly the economy is performing. But it has several shortcomings as a measure of both total output and well-being (total utility).

Nonmarket Activities

Certain productive activities do not take place in any market—the services of stay-at-home parents, for example, and the labor of carpenters who repair their own homes. Such activities never show up in GDP because the accountants who tally up GDP only get data on economic transactions involving *market activities*—that is, transactions in which output or resources are traded for money. Consequently, GDP understates a nation's total output because it does not count *unpaid work*. There is one exception: The portion of farmers' output that farmers consume themselves is estimated and included in GDP.

Leisure

The average workweek (excluding overtime) in the United States has declined since the beginning of the 1900s—from about 53 hours to about 35 hours. Moreover, the greater frequency of paid vacations, holidays, and leave time has

shortened the work year itself. This increase in leisure time has clearly had a positive effect on overall well-being. But our system of national income accounting understates well-being by ignoring leisure's value. Nor does the system accommodate the satisfaction—the “psychic income”—that many people derive from their work.

Improved Product Quality

Because GDP is a quantitative measure rather than a qualitative measure, it fails to capture the full value of improvements in product quality. A \$200 cell phone purchased today is of very different quality than a cell phone that cost \$200 just a decade ago. Today's cell phone is digital and has greater memory capacity, a viewing screen, and quite likely a camera and a music player.

Obviously quality improvement has a great effect on economic well-being, as does the quantity of goods produced. Although the BEA adjusts GDP for quality improvement for selected items, the vast majority of such improvement for the entire range of goods and services does not get reflected in GDP.

The Underground Economy

Embedded in our economy is a flourishing, productive underground sector. Some of the people who conduct business there are gamblers, smugglers, prostitutes, “fences” of stolen goods, drug growers, and drug dealers. They have good reason to conceal their incomes.

Most participants in the underground economy, however, engage in perfectly legal activities but choose illegally not to report their full incomes to the Internal Revenue Service (IRS). A barista at a coffee shop may report just a portion of the tips received from customers. Storekeepers may report only a portion of their sales receipts. Workers who want to hold on to their unemployment compensation benefits may take an “off-the-books” or “cash-only” job. A brick mason may agree to rebuild a neighbor's fireplace in exchange for the neighbor's repairing his boat engine. The value of none of these transactions shows up in GDP.

The value of underground transactions is estimated to be about 8 percent of the recorded GDP in the United States. That would mean that GDP in 2015 was understated by about \$1.4 trillion. Global Perspective 27.2 shows estimates of the relative sizes of underground economies in selected nations.

GDP and the Environment

The growth of GDP is inevitably accompanied by “gross domestic by-products,” including dirty air and polluted water,

GLOBAL PERSPECTIVE 27.2

The Underground Economy as a Percentage of GDP, Selected Nations

Underground economies vary in size worldwide. Three factors that help explain the variation are (1) the extent and complexity of regulation, (2) the type and degree of taxation, and (3) the effectiveness of law enforcement.

Source: Mai Hassan and Friedrich Schneider, "Size and Development of the Shadow Economies of 157 Countries Worldwide: Updated and New Measures from 1999 to 2013," IZA Discussion Paper No. 10281, October 2016, Institute for the Study of Labor (IZA).

toxic waste, congestion, and noise. The social costs of the negative by-products reduce our economic well-being. And since those costs are not deducted from total output, GDP overstates our national well-being. Ironically, when money is spent to clean up pollution and reduce congestion, those expenses are added to GDP!

Composition and Distribution of Output

The composition of output is undoubtedly important for well-being. But GDP does not tell us whether the currently produced mix of goods and services is enriching or potentially detrimental to society. GDP assigns equal weight to an assault rifle and a set of encyclopedias, as long as both sell for the same price. Moreover, GDP reveals nothing about the way output is distributed. Does 90 percent of the output go to 10 percent of the households, for example, or is the output more evenly distributed? The distribution of output may make a big difference for society's overall well-being.

Noneconomic Sources of Well-Being

Finally, the connection between GDP and well-being is problematic for another reason. Just as a household's income does not measure its total happiness, a nation's GDP does not measure its total well-being. Many things could make a society better off without necessarily raising GDP: a reduction of crime and violence, peaceful relations with other countries, people's greater civility toward one another, better understanding between parents and children, and a reduction of drug and alcohol abuse.

The Importance of Intermediate Output

GDP's focus on final output means that it ignores all of the "business to business" economic activity that takes place in the economy at earlier stages of production and distribution. That omission is worrisome because many people's jobs and many firms' profitability depend on economic activity at earlier stages.

Fortunately, a statistic called **gross output (GO)** sums together the dollar value of the economic activity that takes place at each of four stages into which all economic activity can be grouped: resource extraction, production, distribution, and final output (GDP).

Because GO includes GDP (the final stage) as well as the three earlier stages, GO is always larger than GDP. Thus, in 2015, GO was \$31.5 trillion while GDP was \$17.9 trillion.

Because GO takes into account every stage of economic activity, it reflects the overall status of the productive side of the economy better than GDP does. GO is particularly useful when attempting to gauge the magnitude of business cycle fluctuations. During the 2007-2009 recession, real GDP fell 4.2 percent, while real GO fell 8.6 percent. Thus, total economic activity fell by more than twice as much as final output. That substantial difference goes some way toward explaining why employment fell so dramatically during and after the Great Recession.

QUICK REVIEW 27.4

- ✓ GDP is a reasonably accurate and very useful indicator of a nation's economic performance but should not be interpreted as a comprehensive measure of well-being.
- ✓ The major limitations of GDP as an indicator of well-being are that it fails to account for nonmarket and illegal transactions, changes in leisure and in product quality, the composition and distribution of output, the environmental effects of pollution, and economic activity at earlier stages of production and distribution.

Magical Mystery Tour

The Bureau of Economic Analysis (BEA), an Agency of the Department of Commerce, Compiles the NIPA Tables. Where Does It Get the Actual Data?

Discussions of national income accounting often leave the impression that the data for the National Income and Product Accounts magically appear from some mysterious place. Let's take a tour to see where economists get their data.

Consumption The BEA derives the data for the consumption component of the GDP accounts from four main sources:

- The Census Bureau's *Retail Trade Survey*, which gains sales information from a sample of 22,000 firms.
- The Census Bureau's *Survey of Manufacturers*, which gathers information on shipments of consumer goods from 50,000 establishments.
- The Census Bureau's *Service Survey*, which collects sales data from 30,000 service businesses.
- Industry trade sources. For example, data on auto sales and aircraft are collected directly from auto and aircraft manufacturers.

Investment The sources of the data for the investment component of GDP include:

- All the sources above used to determine consumption. Purchases of capital goods are separated from purchases of consumer goods. For example, estimates of investment in equipment and software are based on manufacturers' shipments reported in the *Survey of Manufacturers*, the *Service Survey*, and industry sources.
- Census construction surveys. The Census Bureau's *Housing Starts Survey* and *Housing Sales Survey* produce the data used to measure the amount of housing construction, and the *Construction Progress Reporting Survey* is the source of data on nonresidential construction. The BEA determines changes

in business inventories through the *Retail Trade Survey*, the *Wholesale Trade Survey* (of 7,100 wholesale firms), and the *Survey of Manufacturing*.

Government Purchases The data for government purchases (officially "government consumption and investment expenditures") are obtained through the following sources:

- The U.S. Office of Personnel Management, which collects data on wages and benefits, broken out by the private and public sector. Wages and benefits of government employees are the single largest "purchase" by federal, state, and local government.
- The previously mentioned Census Bureau's construction surveys, which break out private and public sector construction expenditures.
- The Census Bureau's *Survey of Government Finance*, which provides data on government consumption and investment expenditures.

Net Exports The BEA determines net exports through two main sources:

- The U.S. Customs Service, which collects data on exports and imports of goods.
- BEA surveys of potential domestic exporters and importers of services, which collect data on exports and imports of services.

SUMMARY

L027.1 Explain how gross domestic product (GDP) is defined and measured.

Gross domestic product (GDP), a basic measure of an economy's economic performance, is the market value of all final goods and services produced within the borders of a nation in a year.

Final goods are those purchased by end users, whereas intermediate goods are those purchased for resale or for further processing or manufacturing. Intermediate goods, nonproduction transactions, and secondhand sales are purposely excluded in calculating GDP.

L027.2 Describe how expenditures on goods and services can be summed to determine GDP.

GDP may be calculated by summing total expenditures on all final output or by summing the income derived from the production of that output.

By the expenditures approach, GDP is determined by adding consumer purchases of goods and services, gross investment spending by businesses, government purchases, and net exports: $GDP = C + I_g + G + X_n$.

Personal consumption expenditures consist of expenditures on goods (durable goods and nondurable goods) and services. About 60 percent of consumer expenditures in the United States are on services, leading economists to refer to the U.S. economy as a *service economy*.

Gross investment is divided into (a) replacement investment (required to maintain the nation's stock of capital at its existing level) and (b) net investment (the net increase in the stock of capital). In most years, net investment is positive and therefore the economy's stock of capital and production capacity increase.

L027.3 Explain how GDP can be determined by summing up all of the incomes that were derived from producing the economy's output of goods and services.

By the income or allocations approach, GDP is calculated as the sum of compensation to employees, rents, interest, proprietors' income, corporate profits, taxes on production and imports *minus* net foreign factor income, *plus* consumption of fixed capital and a statistical discrepancy.

L027.4 Describe the relationships among GDP, net domestic product, national income, personal income, and disposable income.

Other national accounts are derived from GDP. Net domestic product (NDP) is GDP less the consumption of fixed capital. National income (NI) is total income earned by a nation's resource suppliers plus taxes on production and imports; it is found by subtracting a statistical discrepancy from NDP and adding net foreign factor income to NDP. Personal income (PI) is the total income paid to households prior to any allowance for personal taxes. Disposable income (DI) is personal income after personal taxes have been paid. DI measures the amount of income available to households to consume or save.

L027.5 Discuss the nature and function of a GDP price index and describe the difference between nominal GDP and real GDP.

Price indexes are computed by dividing the price of a specific collection or market basket of output in a particular period by the price of the same market basket in a base period and multiplying the result (the quotient) by 100. The GDP price index is used to adjust nominal GDP for inflation or deflation and thereby obtain real GDP.

Nominal (current-dollar) GDP measures each year's output valued in terms of the prices prevailing in that year. Real (constant-dollar) GDP measures each year's output in terms of the prices that prevailed in a selected base year. Because real GDP is adjusted for price-level changes, differences in real GDP are due only to differences in production activity.

L027.6 List and explain some limitations of the GDP measure.

GDP is a reasonably accurate and very useful indicator of a nation's economic performance, but it has its limitations. It fails to account for nonmarket and illegal transactions, changes in leisure and in product quality, the composition and distribution of output, the environmental effects of pollution, and economic activity at earlier stages of production and distribution. GDP should not be interpreted as a complete measure of well-being.

DISCUSSION QUESTIONS

- In what ways are national income statistics useful? **L027.1**
- Why do national income accountants compare the market value of the total outputs in various years rather than actual physical volumes of production? What problem is posed by any comparison over time of the market values of various total outputs? How is this problem resolved? **L027.1**
- Which of the following goods are usually intermediate goods and which are usually final goods: running shoes, cotton fibers, watches, textbooks, coal, sunscreen lotion, lumber? **L027.1**
- Why do economists include only final goods and services when measuring GDP for a particular year? Why don't they include the value of the stocks and bonds bought and sold? Why don't they include the value of the used furniture bought and sold? **L027.1**
- Explain why an economy's output, in essence, is also its income. **L027.1**
- Provide three examples of each: consumer durable goods, consumer nondurable goods, and services. **L027.2**
- Why are changes in inventories included as part of investment spending? Suppose inventories declined by \$1 billion during 2014. How would this affect the size of gross private domestic investment and gross domestic product in 2014? Explain. **L027.2**
- What is the difference between gross private domestic investment and net private domestic investment? If you were to determine net domestic product (NDP) through the expenditures approach, which of these two measures of investment spending would be appropriate? Explain. **L027.2**
- Use the concepts of gross investment and net investment to distinguish between an economy that has a rising stock of capital and one that has a falling stock of capital. Explain: "Though net investment can be positive, negative, or zero, it is impossible for gross investment to be less than zero." **L027.2**
- Define net exports. Explain how U.S. exports and imports each affects domestic production. How are net exports determined? Explain how net exports might be a negative amount. **L027.2**
- Contrast the ideas of nominal GDP and real GDP. Why is one more reliable than the other for comparing changes in the standard of living over a series of years? What is the GDP price index and what is its role in differentiating nominal GDP and real GDP? **L027.5**
- Which of the following are included or excluded in this year's GDP? Explain your answer in each case. **L027.6**
 - Interest received on an AT&T corporate bond.
 - Social Security payments received by a retired factory worker.
 - Unpaid services of a family member in painting the family home.
 - Income of a dentist from the dental services provided.
 - A monthly allowance a college student receives from home.
 - Money received by Josh when he resells his nearly brand-new Honda automobile to Kim.
 - The publication and sale of a new college textbook.
 - An increase in leisure resulting from a 2-hour decrease in the length of the workweek, with no reduction in pay.
 - A \$2 billion increase in business inventories.
 - The purchase of 100 shares of Google stock.
- Why does gross output do a better job than GDP of measuring overall economic activity? How could you construct a new statistic that focused only on non-final economic activity? Given what you know about the behavior of GO and GDP during the Great Recession, would you expect your new statistic to show more or less volatility than GO and GDP? Why? How would you rank the three in terms of volatility? **L027.6**

- Which of the following transactions would count in GDP? **L027.1**
Select one or more answers from the choices shown.
 - Kerry buys a new sweater to wear this winter.
 - Patricia receives a Social Security check.
 - Roberto gives his daughter \$50 for her birthday.
 - Latika sells \$1,000 of General Electric stock.
 - Karen buys a new car.
 - Amy buys a used car.
- A small economy starts the year with \$1 million in capital. During the course of the year, gross investment is \$150,000 and depreciation is \$50,000. How big is the economy's stock of capital at the end of the year? **L027.2**
 - \$1,150,000.
 - \$1,100,000.
 - \$1,000,000.
 - \$850,000.
 - \$800,000.
- Suppose that this year a small country has a GDP of \$100 billion. Also assume that $I_g = \$30$ billion, $C = \$60$ billion, and $X_n = -\$10$ billion. How big is G ? **L027.3**
 - \$0.
 - \$10 billion.
 - \$20 billion.
 - \$30 billion.

5. Suppose that California imposes a sales tax of 10 percent on all goods and services. A Californian named Ralph then goes into a home improvement store in the state capital of Sacramento and buys a leaf blower that is priced at \$200. With the 10 percent sales tax, his total comes to \$220. How much of the \$220 paid by Ralph will be counted in the national income and product accounts as private income (employee compensation, rents, interest, proprietor's income, and corporate profits)? **L027.3**
- \$220.
 - \$200.
 - \$180.
 - None of the above.
6. Suppose GDP is \$16 trillion, with \$10 trillion coming from consumption, \$2 trillion coming from gross investment, \$3.5 trillion coming from government expenditures, and \$500 billion coming from net exports. Also suppose that across the whole economy, depreciation (consumption of fixed capital) totals \$1 trillion. From these figures, we see that net domestic product equals: **L027.4**
- \$17.0 trillion.
 - \$16.0 trillion.
 - \$15.5 trillion.
 - None of the above.
7. Suppose GDP is \$15 trillion, with \$8 trillion coming from consumption, \$2.5 trillion coming from gross investment, \$3.5 trillion coming from government expenditures, and \$1 trillion coming from net exports. Also suppose that across the whole economy, personal income is \$12 trillion. If the government collects \$1.5 trillion in personal taxes, then disposable income will be: **L027.4**
- \$13.5 trillion.
 - \$12.0 trillion.
 - \$10.5 trillion.
 - None of the above.
8. Suppose that this year's nominal GDP is \$16 trillion. To account for the effects of inflation, we construct a price-level index in which an index value of 100 represents the price level 5 years ago. Using that index, we find that this year's real GDP is \$15 trillion. Given those numbers, we can conclude that the current value of the index is: **L027.5**
- Higher than 100.
 - Lower than 100.
 - Still 100.
9. Which of the following items will be included in official U.S. GDP statistics? **L027.6**
- Select one or more answers from the choices shown.*
- Revenue generated by illegal marijuana growers in Oregon.
 - Money spent to clean up a local toxic waste site in Ohio.
 - Revenue generated by legal medical marijuana sales in California.
 - The dollar value of the annoyance felt by local citizens living near a noisy airport in Georgia.
 - Robert paying Ted for a haircut in Chicago.
 - Emily and Rhonda trading an hour of dance lessons for a haircut in Dallas.
10. Suppose GDP is \$5.0 trillion, resource extraction is \$0.5 trillion, production is \$1.5 trillion, and distribution is \$1.0 trillion. **L027.6**
- How big is GO?
 - How big is GO minus GDP?

PROBLEMS

1. Suppose that annual output in year 1 in a 3-good economy is 3 quarts of ice cream, 1 bottle of shampoo, and 3 jars of peanut butter. In year 2, the output mix changes to 5 quarts of ice cream, 2 bottles of shampoo, and 2 jars of peanut butter. If the prices in both years are \$4 per quart for ice cream, \$3 per bottle of shampoo, and \$2 per jar of peanut butter, what was the economy's GDP in year 1? What was its GDP in year 2? **L027.1**
2. Assume that a grower of flower bulbs sells its annual output of bulbs to an Internet retailer for \$70,000. The retailer, in turn, brings in \$160,000 from selling the bulbs directly to final customers. What amount would these two transactions add to personal consumption expenditures and thus to GDP during the year? **L027.1**
3. If in some country personal consumption expenditures in a specific year are \$50 billion, purchases of stocks and bonds are \$30 billion, net exports are – \$10 billion, government purchases are \$20 billion, sales of secondhand items are \$8 billion, and gross investment is \$25 billion, what is the country's GDP for the year? **L027.2**
4. Below is a list of domestic output and national income figures for a certain year. All figures are in billions. The questions that follow ask you to determine the major national income measures by both the expenditures and the income approaches. The results you obtain with the different methods should be the same. **L027.4**

Personal consumption expenditures	\$245

8. Assume that the total value of the following items is \$600 billion in a specific year for Upper Mongoose: net exports = \$50 billion; value of new goods and services produced in the underground economy = \$75 billion; personal consumption expenditures = \$300 billion; value of the services of stay-at-home parents = \$25 billion; gross domestic investment = \$100 billion; government purchases = \$50 billion. What is Upper Mongoose's GDP for the year? What is the size of the underground economy as a percentage of GDP? By what percentage would GDP be boosted if the value of the services of stay-at-home spouses were included in GDP? **LO27.6**

Economic Growth

Learning Objectives

- LO28.1** List two ways that economic growth is measured.
- LO28.2** Define “modern economic growth” and explain the institutional structures needed for an economy to experience it.
- LO28.3** Identify the general supply, demand, and efficiency forces that give rise to economic growth.
- LO28.4** Describe “growth accounting” and the specific factors accounting for economic growth in the United States.
- LO28.5** Explain how the average rate of U.S. productivity growth has fluctuated since 1973.
- LO28.6** Discuss differing perspectives as to whether growth is desirable and sustainable.

People living in rich countries tend to take economic growth and rising standards of living for granted. Recessions—periods during which output declines—are normally

infrequent and temporary, usually lasting less than a year. Once they pass, modern capitalistic economies return to growing, and living standards continue their seemingly inexorable rise.

But a look back at history or a look around the world today quickly dispels any confidence that economic growth and rising standards of living are automatic or routine. Historically, continually rising living standards are a recent phenomenon, seen only during the last century or two. Before that time, living standards barely rose—if at all—from one generation to the next. And a look around the world today reveals huge differences in standards of living resulting from the disturbing fact that, although some countries have enjoyed decades or even centuries of steadily rising per capita income levels, other countries have experienced hardly any economic growth at all.

This chapter investigates the causes of economic growth, what institutional structures appear to promote economic growth, and the controversies surrounding the benefits and costs of economic growth. As you will see, economic growth has been perhaps the most revolutionary and powerful force in history. Consequently, no study of economics is complete without a thorough understanding of the causes and consequences of economic growth.

Economic Growth

L028.1 List two ways that economic growth is measured.

Economists define and measure **economic growth** as either:

- An increase in real GDP occurring over some time period.
- An increase in real GDP per capita occurring over some time period.

With either definition, economic growth is calculated as a percentage rate of growth per quarter (3-month period) or per year. For the first definition, for example, real GDP in the United States was \$15,961.7 billion in 2014 and \$16,348.9 in 2015. So the U.S. economic growth rate for 2015 was 2.4 percent $\{= [(16,348.9 \text{ billion} - 15,961.7 \text{ billion}) / 15,961.7 \text{ billion}] \times 100\}$. Growth rates normally are positive, but not always. In recession year 2009, for instance, the U.S. rate of economic growth was a *minus* 2.4 percent.

The second definition of economic growth in the bulleted list takes into consideration the size of the population. **Real GDP per capita** (or per capita output) is the amount of real output per person in a country. It is calculated, as follows.

$$\text{Real GDP per capita} = \frac{\text{Real GDP}}{\text{Population}}$$

For example, in 2014 the real GDP in the United States was \$15,961.7 billion and population was 319.4 million. Therefore, real GDP per capita in that year was \$49,974. In 2015 real GDP per capita increased to \$50,820. So the growth rate of real GDP per capita in 2015 was 1.7 percent $\{= [(\$50,820 - \$49,974) / \$49,974] \times 100\}$. In contrast, real GDP per capita fell by 3.3 percent in recession year 2009.

For measuring expansion of military potential or political preeminence, the growth of real GDP is more useful. Unless specified otherwise, growth rates reported in the news and by international agencies use this definition of economic growth. For comparing living standards, however, the second definition is superior. While China's GDP in 2015 was \$10,983 billion compared with Denmark's \$295 billion, Denmark's real GDP per capita was \$64,186 compared with China's strikingly lower \$8,211. And in some cases real GDP growth statistics can be misleading, even when accurate. The African nation of Eritrea had real GDP growth of 1.3 percent per year from 2000–2008. But over the same period its annual growth of population was 3.8 percent, resulting in a decline in real GDP per capita of roughly 2.5 percent per year.

Growth as a Goal

Growth is a widely held economic goal. The expansion of total output relative to population results in rising real wages and incomes and thus higher standards of living. An economy that is experiencing economic growth is better able to meet people's wants and resolve socioeconomic problems. Rising

real wages and income provide richer opportunities to individuals and families—a vacation trip, a personal computer, a higher education—without sacrificing other opportunities and pleasures. A growing economy can undertake new programs to alleviate poverty, embrace diversity, cultivate the arts, and protect the environment without impairing existing levels of consumption, investment, and public goods production.

In short, *growth lessens the burden of scarcity*. A growing economy, unlike a static economy, can consume more today while increasing its capacity to produce more in the future. By easing the burden of scarcity—by relaxing society's constraints on production—economic growth enables a nation to attain its economic goals more readily and to undertake new endeavors that require the use of goods and services to be accomplished.

Arithmetic of Growth

Why do economists pay so much attention to small changes in the rate of economic growth? Because those changes really matter! For the United States, with a current nominal GDP of about \$17.9 trillion, the difference between a 3 percent and a 4 percent rate of growth is about \$179 billion of output each year. For a poor country, a difference of one-half of a percentage point in the rate of growth may mean the difference between starvation and mere hunger.

The mathematical approximation called the **rule of 70** provides a quantitative grasp of the effect of economic growth. The rule of 70 tells us that we can find the number of years it will take for some measure to double, given its annual percentage increase, by dividing that percentage increase into the number 70:

$$\begin{array}{l} \text{Approximate} \\ \text{number of years} \\ \text{required to double} \\ \text{real GDP} \end{array} = \frac{70}{\text{annual percentage rate} \\ \text{of growth}}$$

Examples: A 3 percent annual rate of growth will double real GDP in about 23 ($= 70 \div 3$) years. Growth of 8 percent per year will double real GDP in about 9 ($= 70 \div 8$) years. The rule of 70 is applicable generally. For example, it works for estimating how long it will take the price level or a savings account to double at various percentage rates of inflation or interest. When compounded over many years, an apparently small difference in the rate of growth thus becomes highly significant. Suppose China and Italy start with identical GDPs, but then China grows at an 8 percent yearly rate, while Italy grows at 2 percent. China's GDP would double in about 9 years, while Italy's GDP would double in 35 years.

Growth in the United States

Table 28.1 gives an overview of economic growth in the United States since 1950. Column 2 reveals strong growth as

measured by increases in real GDP. Note that between 1950 and 2015 real GDP increased more than sevenfold. But the U.S. population also increased. Nevertheless, in column 4 we find that real GDP per capita rose more than threefold over these years.

What has been the *rate* of U.S. growth? Real GDP grew at an annual rate of about 3.1 percent between 1950 and 2015. Real GDP per capita increased at roughly 2.0 percent per year over that time. But we must qualify these raw numbers in several ways:

- **Improved products and services** Since the numbers in Table 28.1 do not fully account for improvements in products and services, they understate the growth of economic well-being. Such purely quantitative data do not fully compare an era of vacuum tube computers and low-efficiency V8 hot rods with an era of digital cell phone networks and fuel-sipping, hybrid-drive vehicles.
- **Added leisure** The increases in real GDP and per capita GDP identified in Table 28.1 were accomplished despite increases in leisure. The average workweek, once 50 hours, is now about 35 hours (excluding overtime hours). Again the raw growth numbers understate the gain in economic well-being.
- **Other impacts** These measures of growth do not account for any effects growth may have had on the environment and the quality of life. If growth debases the physical environment, excessively warms the planet, and creates a stressful work environment, the bare growth numbers will overstate the gains in well-being that result from growth. On the other hand, if growth

leads to stronger environmental protections or a more secure and stress-free lifestyle, these numbers will understate the gains in well-being.

In Chapter 26, we made two other key points about U.S. growth rates. First, they are not constant or smooth over time. Like those of other countries, U.S. growth rates vary quarterly and annually depending on a variety of factors such as the introduction of major new inventions and the economy's current position in the business cycle. Second, many countries share the U.S. experience of positive and ongoing economic growth. But sustained growth is both a historically new occurrence and also one that is not shared equally by all countries.

QUICK REVIEW 28.1

- ✓ Economists measure economic growth as either (a) an increase in real GDP over time or (b) an increase in real GDP per capita over time.
- ✓ Real GDP in the United States has grown at an average annual rate of about 3.1 percent since 1950; real GDP per capita has grown at roughly a 2 percent annual rate over that same period.

Modern Economic Growth

LO28.2 Define “modern economic growth” and explain the institutional structures needed for an economy to experience it. We now live in an era of wireless high-speed Internet connections, genetic engineering, and space exploration. New inventions and new technologies drive continual economic growth and ongoing increases in living standards. But it wasn't always like this. Economic growth and sustained increases in living standards are a historically recent phenomenon that started with the Industrial Revolution of the late 1700s. Before the Industrial Revolution, living standards were basically flat over long periods of time so that, for instance, Greek peasants living in the year 300 B.C. had about the same material standard of living as Greek peasants living in the year A.D. 1500. By contrast, our current era of **modern economic growth** is characterized by sustained and ongoing increases in living standards that can cause dramatic increases in the standard of living within less than a single human lifetime.

Economic historians informally date the start of the Industrial Revolution to the year 1776, when the Scottish inventor James Watt perfected a powerful and efficient steam engine. This steam engine inaugurated the modern era since the device could be used to drive industrial factory equipment, steamships, and steam locomotives.

The new industrial factories mass-produced goods for the first time. This meant that nearly all manufacturing shifted from items produced by hand by local craftsmen to items

mass-produced in distant factories. The new steamships and steam locomotives meant that resources could easily flow to factories and that the products of factories could be shipped to distant consumers at low cost. The result was a huge increase in long-distance trade and a major population shift as people left farms to go work in the towns and cities where the new industrial factories were concentrated.

Steam power would later be largely replaced by electric power, and many more inventions would follow the steam engine that started the Industrial Revolution. These included railroads, motorized vehicles, telephones, airplanes, container ships, computers, the Internet, and many more. But the key point is that the last 200 or so years of history have been fundamentally different from anything that went before.

The biggest change has been change itself. Whereas in earlier times material standards of living and the goods and services that people produced and consumed changed very little even over the course of an entire human life span, today people living in countries experiencing modern economic growth are constantly exposed to new technologies, new products, and new services.

What is more, modern economic growth has vastly affected cultural, social, and political arrangements.

- Culturally, the vast increases in wealth and living standards have allowed ordinary people for the first time in history to have significant time for leisure activities and the arts.
- Socially, countries experiencing modern economic growth have abolished feudalism, instituted universal public education, and largely eliminated ancient social norms and legal restrictions against women and minorities doing certain jobs or holding certain positions.
- Politically, countries experiencing modern economic growth have tended to move toward democracy, a form of government that was extremely rare before the start of the Industrial Revolution.

In addition, the average human lifespan has more than doubled, from an average of less than 30 years before modern economic growth began in the late 1700s to a worldwide average of over 71 years today. Thus, for the first time in world history, the average person can expect to live into old age. These and other changes speak to the truly revolutionary power of economic growth and naturally lead economists to consider the causes of economic growth and what policies could be pursued to sustain and promote it. Their desire is intensified by the reality that economic growth is distributed so unevenly around the world.

The Uneven Distribution of Growth

Modern economic growth has spread only slowly from its British birthplace. It first advanced to France, Germany, and other parts of western Europe in the early 1800s before

spreading to the United States, Canada, and Australia by the mid-1800s. Japan began to industrialize in the 1870s, but the rest of Asia did not follow until the early to mid-1900s, at which time large parts of Central and South America as well as the Middle East also began to experience modern economic growth. Most recent has been Africa, which for the most part did not experience modern economic growth until the last few decades. Notably, some parts of the world have yet to experience modern economic growth at all.

The different starting dates for modern economic growth in various parts of the world are the main cause of the vast differences in per capita GDP levels seen today. The current huge gaps between rich countries like the United States and Japan and poor countries like North Korea and Burundi were shown previously in Global Perspective 26.1. But the huge divergence in living standards caused by the fact that different countries started modern economic growth at different times is best seen in Figure 28.1, which shows how GDP per capita has evolved since 1820 in the United States, western Europe, Latin America, Asia, and Africa.

To make the comparison of living standards easier, income levels in all places and at all times have been converted into 1990 U.S. dollars. Using this convention, it is clear that in 1820 per capita incomes in all areas were quite similar, with the richest area in the world in 1820, western Europe, having an average per capita income of \$1,232, while the poorest area of the world at that time, Africa, had an average per capita income of \$418. Thus, in 1820, average incomes in the richest area were only about three times larger than those in the poorest area.

But because western Europe and the United States started experiencing modern economic growth earlier than other areas, they have now ended up vastly richer than other areas, despite the fact that per capita incomes in nearly all places have increased at least a bit. For instance, per capita GDP in the United States in 1998 was \$27,331 while it was only \$1,368 in Africa. Thus, because modern economic growth has occurred for nearly two centuries in the United States compared to a few decades in Africa, average living standards in the United States in 1998 were nearly 20 times higher than those in Africa.

Catching Up Is Possible

Do not get the wrong impression looking at Figure 28.1. Countries that began modern economic growth more recently are *not* doomed to be permanently poorer than the countries that began modern economic growth at an earlier date. This is true because people can adopt technology more quickly than they can invent it. Broadly speaking, the richest countries today have achieved that status because they have the most advanced technology. But because they already have the most advanced technology, they must invent new technology to get

FIGURE 28.1 The great divergence in standards of living. Income levels around the world were very similar in 1820. But they are now very different because certain areas, including the United States and western Europe, began experiencing modern economic growth much earlier than other areas.

even richer. Because inventing and implementing new technology is slow and costly, real GDP per capita in the richest **leader countries** typically grows by an average annual rate of just 2 or 3 percent per year.

By contrast, poorer **follower countries** can grow much faster because they can simply adopt existing technologies from rich leader countries. For instance, in many places in Africa today, the first telephones most people have ever been able to use are cell phones. That is, these countries have not even bothered to install the copper wires necessary for land-line telephones, which are basically a nineteenth-century technology. Instead, they have gone directly for Internet-capable mobile phone networks, a twenty-first-century technology. By doing so, they skip past many stages of technology and development that the United States and other currently rich countries had to pass through. In effect, they jump directly to the most modern, most highly productive technology. The result is that, under the right circumstances, it is possible for poorer countries to experience extremely rapid increases in living standards. This can continue until they have caught up with the leader countries and become leader countries themselves. Once that happens, their growth rates fall down to the 2 or 3 percent rate typical of leader countries. This happens because once they are also rich and using the latest technology, their growth rates are limited by the rate at which new technology can be invented and applied.

Table 28.2 shows both how the growth rates of leader countries are constrained by the rate of technological prog-

ress as well as how certain follower countries have been able to catch up by adopting more advanced technologies and growing rapidly. Table 28.2 shows real GDP per capita in 1960 and 2010 as well as the average annual growth rate of

real GDP per capita between 1960 and 2010 for three countries—the United States, the United Kingdom, and France—that were already rich leader countries in 1960 as well as for five other nations that were relatively poor follower countries at that time. To make comparisons easy, the GDPs and GDPs per capita for all countries are expressed in terms of 2005 U.S. dollars. The countries are ordered by their respective GDPs per capita in 1960, so that the richest country in the world at the time, the United States, is listed first while the poorest of the eight selected countries at the time, South Korea, is listed last.

First, notice that the average annual growth rates of the three leader countries—the United States, the United Kingdom, and France—have all been between 2.1 and 2.5 percent per year because their growth rates are limited by the rate at which new technologies can be invented and applied. By contrast, the five countries that were follower countries in 1960 have been able to grow much faster, between 3.3 percent per year and 5.4 percent per year. This has had remarkable effects on their standards of living relative to the leader countries. For instance, Ireland's GDP per capita was only 60 percent that of its neighbor, the United Kingdom, in 1960. But because Ireland grew at a 3.3 percent rate for the next 50 years while the United Kingdom grew at only a 2.2 percent rate over that time period, by 2010 Ireland's GDP per capita was actually higher than the United Kingdom's GDP per capita. Ireland had become a leader country, too.

The growth experiences of the other four nations that were poor in 1960 have been even more dramatic. Hong Kong, for instance, moved from a GDP per capita that was less than one-third of that enjoyed by the United Kingdom in 1960 to a GDP per capita 13 percent higher than that of the United Kingdom in 2010. The Consider This box emphasizes both how quickly small differences in growth rates can change the level of real GDP per capita and how countries stand in relation to each other in terms of real GDP per capita.

Finally, you may be puzzled as to why the GDP per capita of the United States in 2010 in Table 28.2 is so much higher than that of other rich leader countries. Why, for instance, is U.S. GDP per capita 32 percent higher than French GDP per capita? One important reason is that U.S. citizens put in substantially more labor time than do the citizens of most other leader countries. First, a much larger fraction of the U.S. population is employed than in other rich leader countries. Second, U.S. employees work many more hours per year than do employees in other rich leader countries. For example, 58 percent of the working-age population of the United States was employed in 2010 compared to 51 percent in France. That's a difference of about 14 percent. And American employees worked an average of 1,778 total hours during 2010, compared to an average of 1,478 total hours for French workers. That's a difference of about 20 percent. Added together,

Economic Growth Rates Matter!

When compounded over many decades, small absolute differences in rates of economic growth add up to substantial differences in real GDP and standards of living.

Consider three hypothetical countries—Slogo, Sumgo, and Speedo. Suppose that in 2014 these countries have identical levels of real GDP (\$6 trillion), population (200 million), and real GDP per capita (\$30,000). Also, assume that annual real GDP growth is 2 percent in Slogo, 3 percent in Sumgo, and 4 percent in Speedo.

How will these alternative growth rates affect real GDP and real GDP per capita over a long period, say, a 70-year life-span? By 2084 the 2, 3, and 4 percent growth rates would boost real GDP from \$6 trillion to:

- \$24 trillion in Slogo.
- \$47 trillion in Sumgo.
- \$93 trillion in Speedo.

For illustration, let's assume that each country experienced an average annual population growth of 1 percent over the 70 years. Then, in 2084 real GDP per capita would be about:

- \$60,000 in Slogo.
- \$118,000 in Sumgo.
- \$233,000 in Speedo.

Even small differences in growth rates matter!

these two differences between U.S. and French labor supply imply about a 34 percent difference in the total number of hours worked in the French and American economies. Thus, differences in labor supply help explain differences between rich leader countries in terms of their differing levels of GDP per person.

Buy why do Americans supply so much more labor than workers in France and some of the other rich leader countries? Explanations put forth by economists include cultural differences regarding the proper balance between work and leisure, stronger unions in France and other rich leader countries, and more generous unemployment and welfare programs in France and other rich leader countries. France and other rich leader countries also tend to have higher tax rates than the United States—something that may significantly discourage employment. And, finally, the legal workweek is shorter in some countries than it is in the United States.

QUICK REVIEW 28.2

- ✓ Before the advent of modern economic growth starting in England in the late 1700s, living standards showed no sustained increases over time.
- ✓ Large differences in standards of living exist today because certain areas like the United States have experienced nearly 200 years of modern economic growth while other areas have had only a few decades of economic growth.
- ✓ Poor follower countries can catch up with and even surpass the living standards of rich leader countries by adopting the cutting-edge technologies and institutions already developed by rich leader countries.
- ✓ Substantial differences in GDP per capita among technologically advanced leader countries are often caused by differences in the amount of labor supplied.

Institutional Structures That Promote Modern Economic Growth

Table 28.2 demonstrates that poor follower countries can catch up and become rich leader countries by growing rapidly. But how does a country start that process and enter into modern economic growth? And once it has started modern economic growth, how does it keep the process going?

Economic historians have identified several institutional structures that promote and sustain modern economic growth. Some structures increase the savings and investment that are needed to fund the construction and maintenance of the huge amounts of infrastructure required to run modern economies. Other institutional structures promote the development of new technologies. And still others act to ensure that resources flow efficiently to their most productive uses. These growth-promoting institutional structures include:

- **Strong property rights** These appear to be absolutely necessary for rapid and sustained economic growth. People will not invest if they believe that thieves, bandits, or a rapacious and tyrannical government will steal their investments or their expected returns.
- **Patents and copyrights** Before patents and copyrights were first issued and enforced, inventors and authors usually saw their ideas stolen before they could profit from them. By giving inventors and authors the exclusive right to market and sell their creations, patents and copyrights give a strong financial incentive to invent and create.
- **Efficient financial institutions** These are needed to channel the savings generated by households toward the

businesses, entrepreneurs, and inventors that do most of society's investing and inventing. Banks as well as stock and bond markets appear to be institutions crucial to modern economic growth.

- **Literacy and widespread education** Without highly educated inventors, new technologies do not get developed. And without a highly educated workforce, it is impossible to implement those technologies and put them to productive use.
- **Free trade** Free trade promotes economic growth by allowing countries to specialize so that different types of output can be produced in the countries where they can be made at the lowest opportunity cost. In addition, free trade promotes the rapid spread of new ideas so that innovations made in one country quickly spread to other countries.
- **A competitive market system** Under a market system, prices and profits serve as the signals that tell firms what to make and how much of it to make. Rich leader countries vary substantially in terms of how much government regulation they impose on markets, but in all cases, firms have substantial autonomy to follow market signals in deciding on current production and in making investments to produce what they believe consumers will demand in the future.

Several other difficult-to-measure factors also influence a nation's capacity for economic growth. The overall social-cultural-political environment of the United States, for example, has encouraged economic growth. Beyond the market system that has prevailed in the United States, the United States also has had a stable political system characterized by democratic principles, internal order, the right of property ownership, the legal status of enterprise, and the enforcement of contracts. Economic freedom and political freedom have been "growth-friendly."

In addition, and unlike some nations, there are virtually no social or moral taboos on production and material progress in the United States. The nation's social philosophy has embraced wealth creation as an attainable and desirable goal and the inventor, the innovator, and the businessperson are accorded high degrees of prestige and respect in American society. Finally, Americans have a positive attitude toward work and risk taking, resulting in an ample supply of willing workers and innovative entrepreneurs. A flow of energetic immigrants has greatly augmented that supply.

The following Consider This box deals with how fast-growing follower countries such as India sometimes alter their growth-related institutional structures as they grow richer. Chapter 42 looks at the special problems of economic growth in developing nations.

Patents and Innovation

It costs U.S. and European drug companies about \$1 billion to research, patent, and safety-test a new drug because literally thousands of candidate drugs fail for each drug that succeeds. The only way to cover these costs is by relying on patent protec-

tions that give a drug's developer the exclusive monopoly right to market and sell the new drug for 20 years following the patent application. The revenues over that time period will hopefully be enough to cover the drug's development costs and—if the drug is popular—generate a profit for the drug company.

Leader and follower countries have gotten into heated disputes over patented drugs, however, because the follower countries have often refused to recognize the patents granted to pharmaceutical companies in rich countries. India, for instance, has allowed local drug companies to copy and sell drugs that were developed by U.S. companies and are still under patent protection in the United States.

That policy benefits Indian consumers because competition among the local drug companies drives down the price to below the monopoly price that would be charged by the patent owner. But the weak patent protections in India have a side effect. They make it completely unprofitable for local drug producers to try to develop innovative new drugs. Local rivals would simply copy the new drugs and sell them at very low prices. So India has recently moved to strengthen its patent protections to try to provide financial incentives to transform its local drug companies from copycats into innovators. But note that the innovative new drugs that may result from the increased patent protections are not without a cost. As patent protections in India are improved, inexpensive local drugs copied from the leader countries will no longer be available to Indian consumers.

Determinants of Growth

L028.3 Identify the general supply, demand, and efficiency forces that give rise to economic growth.

Our discussion of modern economic growth and the institutional structures that promote it has purposely been general. We now want to focus our discussion on six factors that directly affect the *rate* and quality of economic growth. These determinants of economic growth can be grouped

into four supply factors, one demand factor, and one efficiency factor.

Supply Factors

The first four determinants of economic growth relate to the physical ability of the economy to expand. They are:

- Increases in the quantity and quality of natural resources.
- Increases in the quantity and quality of human resources.
- Increases in the supply (or stock) of capital goods.
- Improvements in technology.

Any increases or improvements in these **supply factors** will increase the *potential* size of an economy's GDP. The remaining two factors are necessary for that potential to be fulfilled not just in terms of the overall quantity of output but also in terms of the quality of that output and whether it is properly directed toward producing the items most highly valued by society.

Demand Factor

The fifth determinant of economic growth is the **demand factor**:

- To actually achieve the higher production potential created when the supply factors increase or improve, households, businesses, and the government must also expand their purchases of goods and services so as to provide a market for all the new output that can potentially be produced.

If that occurs, there will be no unplanned increases in inventories and resources will remain fully employed. The demand factor acknowledges that economic growth requires that increases in total spending must occur if we are to actually realize the output gains made available by increased production capacity.

Efficiency Factor

The sixth determinant of economic growth is the **efficiency factor**:

- To reach its full production potential, an economy must achieve economic efficiency as well as full employment.

The economy must use its resources in the least costly way (productive efficiency) to produce the specific mix of goods and services that maximizes people's well-being (allocative efficiency). The ability to expand production, together with the full use of available resources, is not sufficient for achieving maximum possible growth. Also required is the efficient use of those resources.

The supply, demand, and efficiency factors in economic growth are related. Unemployment caused by insufficient total spending (the demand factor) may lower the rate of new capital accumulation (a supply factor) and delay expenditures on research (also a supply factor). Conversely, low spending on investment (a supply factor) may cause insufficient spending (the demand factor) and unemployment. Widespread inefficiency in the use of resources (the efficiency factor) may translate into higher costs of goods and services and thus lower profits, which in turn may slow innovation and reduce the accumulation of capital (supply factors). Economic growth is a dynamic process in which the supply, demand, and efficiency factors all interact.

Production Possibilities Analysis

To put the six factors affecting the rate of economic growth into better perspective, let's use the production possibilities analysis introduced in Chapter 1.

Growth and Production Possibilities Recall that a curve like AB in Figure 28.2 is a production possibilities curve. It indicates the various *maximum* combinations of products an economy can produce with its fixed quantity and quality of natural, human, and capital resources and its stock of technological knowledge. An improvement in any of the supply factors will push the production possibilities curve outward, as from AB to CD .

But the demand factor reminds us that an increase in total spending is needed to move the economy from a point like a on curve AB to any of the points on the higher curve CD . And

FIGURE 28.2 Economic growth and the production possibilities curve. Economic growth is made possible by the four supply factors that shift the production possibilities curve outward, as from AB to CD . Economic growth is realized when the demand factor and the efficiency factor move the economy from points such as a and c that are inside CD to the optimal output point, which is assumed to be point b in this figure.

the efficiency factor reminds us that we need least-cost production and an optimal location on CD for the resources to make their maximum possible dollar contribution to total output. You will recall from Chapter 1 that this “best allocation” is determined by expanding the production of each good until its marginal benefit equals its marginal cost. Here, we assume that this optimal combination of capital and consumer goods occurs at point b . If the efficiency factor is in full effect, then the economy will produce at point b rather than at any other point along curve CD .

Example: The net increase in the size of the labor force in the United States in recent years has been 1.5 to 2 million workers per year. That increment raises the economy's production capacity. But obtaining the extra output that these added workers could produce depends on their success in finding jobs. It also depends on whether or not the jobs are in firms and industries where the workers' talents are fully and optimally used. Society does not want new labor-force entrants to be unemployed. Nor does it want pediatricians working as plumbers or pediatricians producing pediatric services for which marginal costs exceed marginal benefits.

Normally, increases in total spending match increases in production capacity, and the economy moves from a point on the previous production possibilities curve to a point on the expanded curve. Moreover, the competitive market system tends to drive the economy toward productive and allocative efficiency. Occasionally, however, the economy may end up at some point such as c in Figure 28.2. That kind of outcome occurred in the United States during the severe recession of 2007–2009. Real output fell far below the amount of output that the economy could have produced if it had achieved full employment and operated on its production possibilities curve.

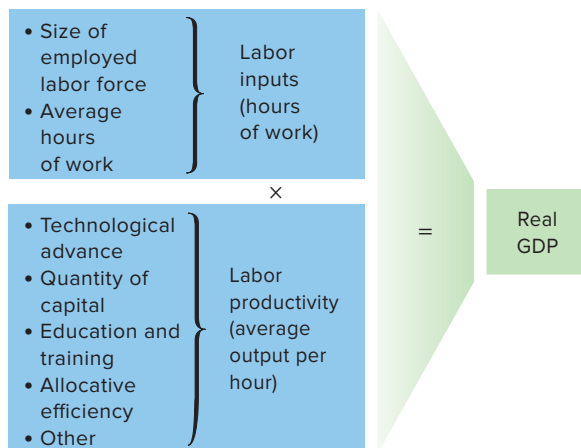

Labor and Productivity Although the demand and efficiency factors are important, discussions of economic growth focus primarily on supply factors. Society can increase its real output and income in two fundamental ways: (1) by increasing its inputs of resources and (2) by raising the productivity of those inputs. Figure 28.3 concentrates on the input of *labor* and provides a useful framework for discussing the role of supply factors in growth. A nation's real GDP in any year depends on the input of labor (measured in hours of work) multiplied by **labor productivity** (measured as real output per hour of work):

$$\text{Real GDP} = \text{hours of work} \times \text{labor productivity}$$

Thought of this way, a nation's economic growth from one year to the next depends on its *increase* in labor inputs (if any) and its *increase* in labor productivity (if any).

Illustration: Assume that the hypothetical economy of Ziam has 10 workers in year 1, each working 2,000 hours per year (50 weeks at 40 hours per week). The total input of labor therefore is 20,000 hours. If productivity (average real output per hour of work) is \$10, then real GDP in Ziam will be \$200,000

FIGURE 28.3 The supply determinants of real output. Real GDP is usefully viewed as the product of the quantity of labor inputs (hours of work) multiplied by labor productivity.

(= 20,000 × \$10). If work hours rise to 20,200 and labor productivity rises to \$10.40, Ziam’s real GDP will increase to \$210,080 in year 2. Ziam’s rate of economic growth will be about 5 percent [= (\$210,080 – \$200,000)/\$200,000] for the year.

Hours of Work What determines the number of hours worked each year? As shown in Figure 28.3, the hours of labor input depend on the size of the employed labor force and the length of the average workweek. Labor-force size depends on the size of the working-age population and the **labor-force participation rate**—the percentage of the working-age population actually in the labor force. The length of the average workweek is governed by legal and institutional considerations and by collective bargaining agreements negotiated between unions and employers.

Labor Productivity Figure 28.3 tells us that labor productivity is determined by technological progress, the quantity of capital goods available to workers, the quality of labor itself, and the efficiency with which inputs are allocated, combined, and managed. Productivity rises when the health, training, education, and motivation of workers improve; when workers

have more and better machinery and natural resources with which to work; when production is better organized and managed; and when labor is reallocated from less-efficient industries to more-efficient industries.

Accounting for Growth

LO28.4 Describe “growth accounting” and the specific factors accounting for economic growth in the United States.

The president’s Council of Economic Advisers uses a system called **growth accounting** to assess the relative importance of the supply-side elements that contribute to changes in real GDP. This system groups these elements into two main categories:

- Increases in hours of work.
- Increases in labor productivity.

Labor Inputs versus Labor Productivity

Table 28.3 provides the relevant data for the United States for five periods. The symbol “Q” in the table stands for “quarter” of the year. The beginning points for the first four periods are business-cycle peaks, and the last period includes future projections by the Council of Economic Advisers. It is clear from the table that both increases in the quantity of labor and increases in labor productivity are important sources of economic growth. Between 1953 and 2015, the labor force increased from 63 million to 158 million workers. Over that period the average length of the workweek remained relatively stable. Falling birthrates slowed the growth of the native population, but increased immigration partly offset that slowdown. As indicated in the nearby Consider This box, of particular significance was a surge of women’s participation in the labor force. Partly as a result, U.S. labor-force growth averaged 1.5 million workers per year over those 62 years.

The growth of labor productivity also has been important to economic growth. In fact, productivity growth has usually been the more significant factor. For example, between 2007 and 2015, labor inputs increased by just 0.1 percent per year. As a result, almost all of the 1.2 percent average annual

growth rate of GDP over that time period was due to increases in labor productivity. As can be calculated from the data in the far right column of Table 28.3, productivity growth is projected to account for 88 percent of the growth of real GDP between 2015 and 2026.

Because increases in labor productivity are so important to economic growth, economists go to the trouble of investigating and assessing the relative importance of the factors that contribute to productivity growth. There are five factors that, together, appear to explain changes in productivity growth rates: technological advance, the amount of capital each worker has to work with, education and training, economies of scale, and resource allocation. We will examine each factor in turn, noting how much each factor contributes to productivity growth.

Technological Advance

The largest contributor to productivity growth is technological advance, which is thought to account for about 40 percent of productivity growth. As economist Paul Romer stated, “Human history teaches us that economic growth springs from better recipes, not just from more cooking.”

Technological advance includes not only innovative production techniques but new managerial methods and new forms of business organization that improve the process of production. Generally, technological advance is generated by the discovery of new knowledge, which allows resources to be combined in improved ways that increase output. Once discovered and implemented, new knowledge soon becomes available to entrepreneurs and firms at relatively low cost. Technological advance therefore eventually spreads through the entire economy, boosting productivity and economic growth.

Technological advance and capital formation (investment) are closely related, since technological advance usually promotes investment in new machinery and equipment. In fact, technological advance is often *embodied* within new capital. For example, the purchase of new computers brings into industry speedier, more powerful computers that incorporate new technology.

Technological advance has been both rapid and profound. Gas and diesel engines, conveyor belts, and assembly lines are significant developments of the past. So, too, are fuel-efficient commercial aircraft, integrated microcircuits, personal computers, digital photography, and containerized shipping. More recently, technological advance has exploded, particularly in the areas of computers, photography, wireless communications, and the Internet. Other fertile areas of recent innovation are medicine and biotechnology.

Quantity of Capital

A second major contributor to productivity growth is increased capital, which explains roughly 30 percent of productivity growth. More and better plant and equipment make workers more productive. And a nation acquires more capital by

Women, the Labor Force, and Economic Growth

The substantial rise in the number of women working in the paid workforce in the United States has been one of the major labor market trends of the last 50 years. In 1960, about 40 percent of women worked full-time or part-time in paid jobs. Today, that number is about 60 percent.

Women have greatly increased their productivity in the workplace, mostly by becoming better educated and professionally trained. Rising productivity has increased women's wage rates. Those higher wages have raised the opportunity costs—the forgone wage earnings—of staying at home. Women have therefore substituted employment in the labor market for traditional home activities. This substitution has been particularly pronounced among married women. (Single women have always had high labor-force participation rates.)

Furthermore, changing lifestyles and the widespread availability of birth control have freed up time for greater labor-force participation by women. Women not only have fewer children, but those children are spaced closer together in age. Thus women who leave their jobs during their children's early years return to the labor force sooner.

Greater access to jobs by women also has raised the labor-force participation of women. Service industries—teaching, nursing, and office work, for instance—that traditionally have employed many women have expanded rapidly in the past several decades. Also, the population in general has shifted from farms and rural regions to urban areas, where jobs for women are more abundant and more geographically accessible. Additionally, occupational barriers to professions have greatly eroded, resulting in many more women becoming business managers, lawyers, professors, and physicians.

In summary, women in the United States are better educated, more productive, and more efficiently employed than ever before. Their greater presence in the labor force has contributed greatly to U.S. economic growth.

saving some of its income and using that savings to invest in plant and equipment.

Although some capital substitutes for labor, most capital is complementary to labor—it makes labor more productive. A key determinant of labor productivity is the amount of capital goods available *per worker*. If both the aggregate stock of capital goods and the size of the labor force increase over a given period, the individual worker is not necessarily better equipped and productivity will not necessarily rise. But the quantity of

FIGURE 28.4 Changes in the educational attainment of the U.S. adult population. The percentage of the U.S. adult population, age 25 or older, completing high school and college has been rising over recent decades.

capital equipment available per U.S. worker has increased greatly over time. (In 2014 it was about \$149,286 per worker.)

Public investment in the U.S. **infrastructure** (highways and bridges, public transit systems, wastewater treatment facilities, water systems, airports, educational facilities, and so on) has also grown over the years. This publicly owned capital complements private capital. Investments in new highways promote private investment in new factories and retail stores along their routes. Industrial parks developed by local governments attract manufacturing and distribution firms.

Private investment in infrastructure also plays a large role in economic growth. One example is the tremendous growth of private capital relating to communications systems over the years.

Education and Training

Ben Franklin once said, “He that hath a trade hath an estate,” meaning that education and training contribute to a worker’s stock of **human capital**—the knowledge and skills that make a worker productive. Investment in human capital includes not only formal education but also on-the-job training. Like investment in physical capital, investment in human capital is an important means of increasing labor productivity and earnings. An estimated 15 percent of productivity growth derives from investments in people’s education and skills.

One measure of a nation’s quality of labor is its level of educational attainment. Figure 28.4 shows large gains in education attainment over the past several decades. In 1960 only 41 percent of the U.S. population age 25 or older had at least a high school education, and only 8 percent had a college or post-college education. By 2015, those numbers had increased to 88 and 33 percent, respectively. Clearly, more people are receiving more education than ever before.

But all is not upbeat with education in the United States. Many observers think that the quality of education in the United States has declined. For example, U.S.

students perform poorly on science and math tests relative to students in many other nations (see Global Perspective 28.1). And the United States has been producing fewer engineers and scientists, a problem that may trace back to inadequate training in math and science in elementary and high schools. For these reasons, much recent public policy discussion and legislation have been directed toward improving the quality of the U.S. education and training system.

Economies of Scale and Resource Allocation

Economies of scale and improved resource allocation are a fourth and fifth source of productivity growth, and together they explain about 15 percent of productivity growth.

Economies of Scale Reductions in per-unit production costs that result from increases in output levels are called **economies of scale**. Markets have increased in size over time, allowing firms to increase output levels and thereby achieve production advantages associated with greater size. As firms expand their size and output, they are able to use larger, more productive equipment and employ methods of manufacturing and delivery that increase productivity. They also are better able to recoup substantial investments in developing new products and production methods. Examples: A large manufacturer of autos can use elaborate assembly lines with computerization and robotics, while smaller producers must settle for less-advanced technologies using more labor inputs. Large pharmaceutical firms greatly reduce the average amount of labor (researchers, production workers) needed to produce each pill as they increase the number of pills produced. Accordingly, economies of scale result in greater real GDP and thus contribute to economic growth.

Improved Resource Allocation Improved resource allocation means that workers over time have moved from low-productivity employment to high-productivity employment. Historically, many workers have shifted from agriculture, where labor productivity is low, to manufacturing, where it is quite high. More recently, labor has shifted away from some manufacturing industries to even higher-productivity industries such as computer software, business consulting, and pharmaceuticals. As a result of such shifts, the average productivity of U.S. workers has increased.

Also, discrimination in education and the labor market has historically deterred some women and minorities from entering high-productivity jobs. With the decline of such discrimination over time, many members of those groups have shifted from lower-productivity jobs to higher-productivity jobs. The result has been higher overall labor productivity and real GDP.

Finally, things such as tariffs, import quotas, and other barriers to international trade tend to relegate resources to relatively unproductive pursuits. The long-run movement toward liberalized international trade through international agreements has improved the allocation of resources, increased labor productivity, and expanded real output, both here and abroad.

QUICK REVIEW 28.3

- ✓ Institutional structures that promote growth include strong property rights, patents, efficient financial institutions, education, and a competitive market system.
- ✓ The determinants of economic growth include four supply factors (increases in the quantity and quality of natural resources, increases in the quantity and quality of human resources, increases in the stock of capital goods, and improvements in technology), one demand factor (increases in total spending), and one efficiency factor (achieving allocative and productive efficiency).
- ✓ Improvements in labor productivity accounted for about two-thirds of the increase in U.S. real GDP between 1990 and 2012; the use of more labor inputs accounted for the remainder.
- ✓ Improved technology, more capital, greater education and training, economies of scale, and better resource allocation have been the main contributors to U.S. productivity growth and thus to U.S. economic growth.

Recent Fluctuations in the Average Rate of Productivity Growth

L028.5 Explain how the average rate of U.S. productivity growth has fluctuated since 1973.

Figure 28.5 shows the growth of labor productivity (as measured by changes in the index of labor productivity) in the United States from 1973 to 2015, along with separate trend lines for 1973–1995, 1995–2010, and 2010–2015. Labor productivity in the business sector grew by an average of only 1.5 percent yearly over the 1973–1995 period. But productivity growth averaged a much higher 2.6 percent per year between 1995 and 2010 before plummeting to just 0.4 percent between 2010 and 2015. Many economists believe that the rapid productivity growth experienced between 1995 and 2010 resulted from a significant new wave of technological advances, coupled with global competition. By contrast, the dramatic decline in productivity growth that followed the Great Recession of 2007–2009 was perhaps due to a slowdown in the rate at which productive new technologies were being implemented by businesses.

Robust productivity growth is important because real output, real income, and real wages are linked to labor productivity. To see why, suppose you are alone on an uninhabited island. The number of fish you can catch or coconuts you can pick per hour—your productivity—is your real wage (or real income) per hour. By *increasing* your productivity, you can improve your standard of living because you can gather more fish and more coconuts (goods) for each hour of work.

FIGURE 28.5 Growth of labor productivity in the United States, 1973–2012. U.S. labor productivity (here, for the business sector) increased at an average annual rate of only 1.5 percent from 1973 to 1995. But between 1995 and 2010, it rose at an annual rate of 2.6 percent before decreasing to just 0.4 percent per year after the Great Recession of 2007–2009.

So it is for the economy as a whole: Over long periods, the economy's labor productivity determines its average real hourly wage, which includes fringe benefits such as health care insurance and contributions to pensions. The economy's income per hour is equal to its output per hour. So productivity growth is the economy's main route for improving the living standards for its workers. It allows firms to pay higher wages without lowering their business profits.

Reasons for the Rise in the Average Rate of Productivity Growth between 1995 and 2010

Why did productivity growth increase rapidly between 1995 and 2010?

The Microchip and Information Technology The core element of the productivity speedup between 1995 and 2010 was an explosion of entrepreneurship and innovation based on the microprocessor, or *microchip*, which bundles transistors on a piece of silicon. Some observers liken the invention of the microchip to that of electricity, the automobile, air travel, the telephone, and television in importance and scope.

The microchip has found its way into thousands of applications. It has helped create a wide array of new products and services and new ways of doing business. Its immediate results were the pocket calculator, the bar-code scanner, the personal computer, the laptop computer, and more powerful business computers. But the miniaturization of electronic circuits also advanced the development of many other products such as cell phones and pagers, computer-guided lasers, global positioning equipment, energy conservation systems,

Doppler radar, digital cameras, and machines to decipher the human genome.

Perhaps of greatest significance, the widespread availability of personal and laptop computers stimulated the desire to tie them together. That desire promoted rapid development of the Internet and all its many manifestations, such as business-to-household and business-to-business electronic commerce (e-commerce). The combination of the computer, fiber-optic cable, wireless technology, and the Internet constitutes a spectacular advance in **information technology**, which has been used to connect all parts of the world.

New Firms and Increasing Returns Hundreds of new **start-up firms** advanced various aspects of the new information technology. Many of these firms created more “hype” than goods and services and quickly fell by the wayside. But a number of firms flourished, eventually to take their places among the nation's largest firms. Examples of those firms include Intel (microchips); Apple and Dell (personal computers); Microsoft and Oracle (computer software); Cisco Systems (Internet switching systems); America Online (Internet service provision); Yahoo and Google (Internet search engines); and eBay, PayPal, and Amazon.com (electronic commerce). There are scores more! Most of these firms were either “not on the radar” or “a small blip on the radar” 30 years ago. Today each of them has large annual revenue and employs thousands of workers.

Successful new firms often experience **increasing returns**, a situation in which a given percentage increase in the amount of inputs a firm uses leads to an even larger percentage increase in the amount of output the firm produces. For example, suppose that a company called Techco decides to

double the size of its operations to meet the growing demand for its services. After doubling its plant and equipment and doubling its workforce, say, from 100 workers to 200 workers, it finds that its total output has tripled from 8,000 units to 24,000 units. Techco has experienced increasing returns; its output has increased by 200 percent, while its inputs have increased by only 100 percent. That is, its labor productivity has gone up from 80 units per worker (= 8,000 units/100 workers) to 120 units per worker (= 24,000 units/200 workers). Increasing returns boost labor productivity and reduce per-unit production costs. Since these cost reductions result from increases in output levels, they are examples of *economies of scale*.

Both emerging firms as well as established firms can exploit several different sources of increasing returns and economies of scale:

- **More specialized inputs** Firms can use more specialized and thus more productive capital and workers as they expand their operations. A growing new e-commerce business, for example, can purchase highly specialized inventory management systems and hire specialized personnel such as accountants, marketing managers, and system maintenance experts.
- **Spreading of development costs** Firms can spread high product development costs over greater output. For example, suppose that a new software product costs \$100,000 to develop and only \$2 per unit to manufacture and sell. If the firm sells 1,000 units of the software, its per-unit cost will be \$102 [= $(\$100,000 + \$2,000)/1,000$], but if it sells 500,000 units, that cost will drop to only \$2.20 [= $(\$100,000 + \$1 \text{ million})/500,000$].
- **Simultaneous consumption** Many recently developed products and services can satisfy large numbers of customers at the same time. Unlike a gallon of gas that needs to be produced for each buyer, a software program needs to be produced only once. It then becomes available at very low expense to thousands or even millions of buyers. The same is true of books delivered to electronic reading devices, movies distributed on DVDs, and information disseminated through the Internet.
- **Network effects** Software and Internet service become more beneficial to a buyer the greater the number of households and businesses that also buy them. When others have Internet service, you can send e-mail messages to them. And when they also have software that allows display of documents and photos, you can attach those items to your e-mail messages. These interconnectivity advantages are called **network effects**, which are increases in the value of a product to each user, including existing users, as the total number of users rises. The domestic and global expansion of

the Internet in particular has produced network effects, as have cell phones, pagers, tablet computers, and other aspects of wireless communication. Network effects magnify the value of output well beyond the costs of inputs.

- **Learning by doing** Finally, firms that produce new products or pioneer new ways of doing business experience increasing returns through **learning by doing**. Tasks that initially may have taken firms hours may take them only minutes once the methods are perfected.

Whatever the particular source of increasing returns, the result is higher productivity, which tends to reduce the per-unit cost of producing and delivering products.

Global Competition The recent economy is characterized not only by information technology and increasing returns but also by heightened global competition. The collapse of the socialist economies in the late 1980s and early 1990s, together with the success of market systems, has led to a reawakening of capitalism throughout the world. The new information technologies have “shrunk the globe” and made it imperative for all firms to lower their costs and prices and to innovate in order to remain competitive. Free-trade zones such as NAFTA and the European Union (EU), along with trade liberalization through the World Trade Organization (WTO), have also heightened competition internationally by removing trade protection from domestic firms. The larger geographic markets, in turn, have enabled firms to expand beyond their national borders.

Implications for Economic Growth

Other things equal, stronger productivity growth and heightened global competition allow the economy to achieve a higher rate of economic growth. A glance back at Figure 28.2 will help make this point. Suppose that the shift of the production possibilities curve from *AB* to *CD* reflects annual changes in potential output levels before the recent increase in growth rates. Then the higher growth rates of the more recent period of accelerated productivity growth would be depicted by a *larger* outward shift of the economy’s production possibilities from *AB* to a curve beyond *CD*. When coupled with economic efficiency and increased total spending, the economy’s real GDP would rise by even more than what is shown.

The Recent Productivity Slowdown

It is not clear whether the dramatic slowdown in productivity growth that took place after the Great Recession is permanent or transitory. Some economists have argued that the high productivity growth rates observed between 1995 and 2010 were a one-time anomaly due to the information technology revolution. But even if information technology caused an unusual

burst of growth for 15 years, it is still surprising that post-2010 productivity growth rates have been so very low, much lower in fact than the rates that prevailed before the information technology revolution.

By the mid-2010s, several possible explanations had been put forward to explain why productivity growth rates had fallen so low. One possible culprit is the high debt levels that accumulated before the Great Recession. Under this hypothesis, individuals and firms are now too busy paying down debts to make productive investments. At the same time, entrepreneurs who might be able to improve productivity may be unable to obtain loans because banks are reluctant to lend after having made so many bad loans prior to the Great Recession.

Overcapacity may be another possible explanation for the productivity slowdown. During the boom that preceded the Great Recession, worldwide productive capacity increased massively as many new factories were built. But the additional capacity may have exceeded the amount of consumer demand that would have been necessary to purchase the additional output made possible by the additional capacity. If so, firms would have been reluctant to install newer, more

productive equipment or build newer, more productive factories after the Great Recession because they already had more than enough production capacity. Under this hypothesis, productivity stagnated because producers continued to rely on aging machinery and equipment.

Another possible explanation for the slowdown in measured productivity has to do with the fact that many recent products—especially Internet apps—do not generate much of a measurable effect on GDP. Consider Facebook, YouTube, and Instagram. They are for the most part totally free to consumers. So even if billions of people are using these products, measured output won't go up very much because there is no monetary payment being made by users. Under this hypothesis, things aren't so bad. *Measured* productivity growth is low, but the new products are in fact innovative and bring with them a huge amount of consumer surplus; we just can't discern those benefits in the GDP and productivity statistics.

Finally, it is also possible that technological progress itself may have stalled. Under this hypothesis, productivity growth will remain slow until invention and innovation speed up again.

Is Growth Desirable and Sustainable?

L028.6 Discuss differing perspectives as to whether growth is desirable and sustainable.

Economists usually take for granted that economic growth is desirable and sustainable. But not everyone agrees.

The Antigrowth View

Critics of growth say industrialization and growth result in pollution, climate change, ozone depletion, and other environmental problems. These adverse negative externalities

Can Economic Growth Survive Population Decline?

The Demographic Transition Is Causing Greying Populations, Shrinking Labor Forces, and Overall Population Decreases in Many Nations. Can Economic Growth Survive?

As you know from this chapter, $\text{Real GDP} = \text{hours of work} \times \text{labor productivity}$. The number of *hours of work* depends heavily, however, on the size of the working-age population. If it begins to shrink, the number of *hours of work* almost always falls. In such cases, the only way real GDP can rise is if *labor productivity* increases faster than *hours of work* decreases. The world is about to see if that can happen in countries that have populations that are greying and shrinking.

The historical background has to do with the fact that as nations industrialize, their economies shift from agriculture to industry. As that happens, fertility levels plummet because the shift to modern technology transforms children from being economically essential farm hands that can contribute to their families'

incomes from a young age to expensive investment goods that require many years of costly schooling before they can support themselves.

As people react to this change, birthrates tend to fall quite dramatically. The key statistic is the *total fertility rate* that keeps track of the average number of births that women have during their lifetimes. To keep the population stable in modern societies, the total fertility rate must be about 2.1 births per woman per lifetime (= 1 child to replace mom, 1 child to replace dad, and 0.1 child to compensate for those people who never end up reproducing as adults).

Every rich industrial nation has now seen its total fertility rate drop below the replacement level of 2.1 births per woman per lifetime. In Japan and many eastern

occur because inputs in the production process reenter the environment as some form of waste. The more rapid our growth and the higher our standard of living, the more waste the environment must absorb—or attempt to absorb. In an already wealthy society, further growth usually means satisfying increasingly trivial wants at the cost of mounting threats to the ecological system.

Critics of growth also argue that there is little compelling evidence that economic growth has solved sociological problems such as poverty, homelessness, and discrimination. Consider poverty: In the antigrowth view, American poverty is a problem of distribution, not production. The requisite for solving the problem is a firm commitment to redistribute wealth and income, not further increases in output.

Antigrowth sentiment also says that while growth may permit us to “make a better living,” it does not give us “the good life.” We may be producing more and enjoying it less. Growth means frantic paces on jobs, worker burnout, and alienated employees who have little or no control over decisions affecting their lives. The changing technology at the core of growth poses new anxieties and new sources of insecurity for workers. Both high-level and low-level workers

face the prospect of having their hard-earned skills and experience rendered obsolete by onrushing technology. High-growth economies are high-stress economies, which may impair our physical and mental health.

Finally, critics of high rates of growth doubt that they are sustainable. The planet Earth has finite amounts of natural resources available, and they are being consumed at alarming rates. Higher rates of economic growth simply speed up the degradation and exhaustion of the earth’s resources. In this view, slower economic growth that is environmentally sustainable is preferable to faster growth.

In Defense of Economic Growth

The primary defense of growth is that it is the path to the greater material abundance and higher living standards desired by the vast majority of people. Rising output and incomes allow people to buy

more education, recreation, and travel, more medical care, closer communications, more skilled personal and professional services, and better-designed as well as more numerous products. It also means more art, music, and poetry, theater, and

European countries, the number has been so low for so long that there are no longer enough children being born each year to replace the old folks who are dying. As a result, their overall populations are shrinking.

Economists only expect that pattern to become more common and more rapid, so that by the year 2050 the majority of nations will have decreasing populations. But decades before a nation's overall population begins to decrease, it faces a situation in which the labor force shrinks while the elderly population swells.

That pattern is the result of each generation being smaller than the one before. As an example, the baby boom generation born between 1946 and 1964 is much larger than the "baby bust" generation that followed it. So as the boomers retire over the next two decades, there will be a lot of retirees as compared to working-age adults.

This trend can be quantified by the *inverse dependency ratio*, which is defined as the number of people of working age (ages 20 to 64) divided by the number of dependents (seniors over age 65 plus youths under age 20). In the United States, the inverse dependency ratio is set to fall from 1.5 people of working age per dependent in 2010 to just 1.16 people of working age per dependent in 2050. That is extremely problematic because it implies that worker productivity will have to rise dramatically just to make up for the relative decline in the number of workers as compared to dependents. If productivity doesn't keep up with the fall in the inverse dependency ratio, living standards will have to decline because

there will simply be too many nonworking consumers relative to working-age producers.

The place where this problem is likely to show up first is Social Security. There are currently 2.9 workers paying into the Social Security system for each retiree receiving Social Security benefits. But that number is set to fall to just 2.0 workers per retiree in 2030. So worker productivity would have to increase by almost a third in under 20 years just to keep up with the decline in the number of workers relative to retirees.

Economists are uncertain about whether such large productivity increases will be forthcoming. The problem is that consumption competes with investment. A society with a larger fraction of dependents is a society that is likely to devote an increasingly high fraction of total output toward consumption rather than investment. If so, productivity growth may slow considerably.

Another possible problem is that, historically, most transformative new technologies and businesses have been created by energetic young people under the age of 40. With each generation getting smaller, there will be fewer people in that age range and thus, possibly, less innovation and slower productivity growth.

Other economists are more hopeful, however. They view old people as consumers and demanders. As their numbers swell, inventors may simply switch from inventing products for young people to inventing products for old people. If so, productivity growth and living standards could keep on rising at the rates we have come to expect.

drama. It can even mean more time and resources devoted to spiritual growth and human development.¹

Growth also enables society to improve the nation's infrastructure, enhance the care of the sick and elderly, provide greater access for the disabled, and provide more police and fire protection. Economic growth may be the only realistic way to reduce poverty, since there is only limited political support for greater redistribution of income. The way to improve the economic position of the poor is to increase household incomes through higher productivity and economic growth. Also, a no-growth policy among industrial nations might severely limit growth in poor nations. Foreign investment and development assistance in those nations would fall, keeping the world's poor in poverty longer.

Economic growth has not made labor more unpleasant or hazardous, as critics suggest. New machinery is usually less taxing and less dangerous than the machinery it replaces. Air-conditioned workplaces are more pleasant than steamy

workshops. Furthermore, why would an end to economic growth reduce materialism or alienation? The loudest protests against materialism are heard in those nations and groups that now enjoy the highest levels of material abundance! The high standard of living that growth provides has increased our leisure and given us more time for reflection and self-fulfillment.

Does growth threaten the environment? The connection between growth and environment is tenuous, say growth proponents. Increases in economic growth need not mean increases in pollution. Pollution is not so much a by-product of growth as it is a "problem of the commons." Much of the environment—streams, lakes, oceans, and the air—is treated as common property, with insufficient or no restrictions on its use. The commons have become our dumping grounds; we have overused and debased them. Environmental pollution is a case of negative externalities, and correcting this problem involves regulatory legislation, specific taxes ("effluent charges"), or market-based incentives to remedy misuse of the environment.

Those who support growth admit there are serious environmental problems. But they say that limiting growth is the wrong solution. Growth has allowed economies to reduce pollution, be more sensitive to environmental considerations,

set aside wilderness, create national parks and monuments, and clean up hazardous waste, while still enabling rising household incomes. (See the Last Word in Chapter 19.)

Is growth sustainable? Yes, say the proponents of growth. If we were depleting natural resources faster than their discovery, we would see the prices of those resources rise. That has not been the case for most natural resources; in fact, the prices of most of them have declined (see Figure 19.1). And if one natural resource becomes too expensive, another resource will be substituted for it. Moreover, say economists, economic growth has to do with the expansion and application of human knowledge and information, not of extractable natural resources. In this view, economic growth is limited only by human imagination.

QUICK REVIEW 28.5

- ✓ Critics of growth argue that it adds to environmental degradation, increases human stress, and exhausts the earth's finite supply of natural resources.
- ✓ Defenders of growth say that it is the primary path to the rising living standards, that it need not debase the environment, and that there are no indications that we are running out of resources.
- ✓ Defenders of growth argue that it is sustainable because growth is based on the expansion and application of human knowledge, which is limited only by human imagination.

SUMMARY

L028.1 List two ways that economic growth is measured.

A nation's economic growth can be measured either as an increase in real GDP over time or as an increase in real GDP per capita over time. Real GDP in the United States has grown at an average annual rate of about 3.2 percent since 1950; real GDP per capita has grown at roughly a 2 percent annual rate over that same period.

L028.2 Define "modern economic growth" and explain the institutional structures needed for an economy to experience it.

Sustained increases in real GDP per capita did not happen until the past two centuries, when England and then other countries began to experience modern economic growth, which is characterized by institutional structures that encourage savings, investment, and the development of new technologies. Institutional structures that promote growth include strong property rights, patents, efficient financial institutions, education, and a competitive market system.

Because some nations have experienced nearly two centuries of modern economic growth while others have only recently begun to experience modern economic growth, some countries today are much richer than other countries.

It is possible, however, for countries that are currently poor to grow faster than countries that are currently rich because the growth of real GDP per capita for rich countries is limited to about 2 percent per year. To continue growing, rich countries must invent and apply new technologies. By contrast, poor countries can grow much faster because they can simply adopt the institutions and cutting-edge technologies already developed by the rich countries.

L028.3 Identify the general supply, demand, and efficiency forces that give rise to economic growth.

The determinants of economic growth to which we can attribute changes in growth rates include four supply factors (changes in the quantity and quality of natural resources, changes in the quantity and

quality of human resources, changes in the stock of capital goods, and improvements in technology), one demand factor (changes in total spending), and one efficiency factor (changes in how well an economy achieves allocative and productive efficiency).

The growth of a nation's capacity to produce output can be illustrated graphically by an outward shift of its production possibilities curve.

L028.4 Describe "growth accounting" and the specific factors accounting for economic growth in the United States.

Growth accounting attributes increases in real GDP either to increases in the amount of labor being employed or to increases in the productivity of the labor being employed. Increases in U.S. real GDP are mostly the result of increases in labor productivity. The increases in labor productivity can be attributed to technological progress, increases in the quantity of capital per worker, improvements in the education and training of workers, the exploitation of economies of scale, and improvements in the allocation of labor across different industries.

L028.5 Explain how the average rate of U.S. productivity growth has fluctuated since 1973.

Over long time periods, the growth of labor productivity underlies an economy's growth of real wages and its standard of living. U.S. productivity rose by 1.5 percent annually between 1973 and 1995, 2.6 percent annually between 1995 and 2010, and just 0.4 percent annually from 2010 to 2015.

The 1995 to 2010 increase in the average rate of productivity growth was based on (a) rapid technological change in the form of the microchip and information technology, (b) increasing returns and lower per-unit costs, and (c) heightened global competition that holds down prices.

The main sources of increasing returns are (a) the use of more specialized inputs as firms grow, (b) the spreading of development costs, (c) simultaneous consumption by consumers, (d) network

effects, and (e) learning by doing. Increasing returns mean higher productivity and lower per-unit production costs.

Possible explanations for the slow productivity growth rate after the Great Recession of 2007–2008 include high debt levels, overcapacity, the rise of “free” Internet products, and a slowdown in technological innovation.

LO28.6 Discuss differing perspectives as to whether growth is desirable and sustainable.

Skeptics wonder if the recent rise in the average rate of productivity growth is permanent, and suggest a wait-and-see approach.

They point out that surges in productivity and real GDP growth have previously occurred but do not necessarily represent long-lived trends.

Critics of rapid growth say that it adds to environmental degradation, increases human stress, and exhausts the earth’s finite supply of natural resources. Defenders of rapid growth say that it is the primary path to the rising living standards nearly universally desired by people, that it need not debase the environment, and that there are no indications that we are running out of resources. Growth is based on the expansion and application of human knowledge, which is limited only by human imagination.

What will be the per-unit cost of the application if it sells 100 units? 1,000 units? 1 million units? **L028.5**

Business Cycles, Unemployment, and Inflation

Learning Objectives

- LO29.1** Describe the business cycle and its primary phases.
- LO29.2** Illustrate how unemployment is measured and explain the different types of unemployment.
- LO29.3** Explain how inflation is measured and distinguish between cost-push inflation and demand-pull inflation.
- LO29.4** Relate how unanticipated inflation can redistribute real income.
- LO29.5** Discuss how inflation may affect the economy's level of real output.

As indicated in Chapter 28, the United States has experienced remarkable economic growth over time. But this growth has not been smooth, steady, and predictable from year to year. At various times the United States has experienced recessions, high unemployment rates, or high inflation rates. For example, U.S. unemployment rose by 8 million workers and the unemployment rate increased from 4.7 percent to 10.1 percent during the 2007–2009

recession. Other nations have also suffered high unemployment rates at times. As just one example, the Greek unemployment rate exceeded 25 percent in 2015. Also, inflation has occasionally plagued the United States and other nations. For instance, the U.S. inflation rate in 1980 was 13.5 percent while Zimbabwe's inflation rate soared to 26,000 percent in 2007!

Our goal in this chapter is to examine the concepts, terminology, and facts relating to macroeconomic instability. Specifically, we want to discuss the business cycle, unemployment, and inflation. The concepts discussed are extremely important for understanding subsequent chapters on economic theory and economic policy.

The Business Cycle

LO29.1 Describe the business cycle and its primary phases. The long-run trend of the U.S. economy is one of economic growth, as stylized by the upsloping line labeled “Growth Trend” in Figure 29.1. But growth has been interrupted by periods of economic instability usually associated with **business cycles**. Business cycles are alternating rises and declines in the level of economic activity, sometimes over several years. Individual cycles (one “up” followed by one “down”) vary substantially in duration and intensity.

FIGURE 29.1 The business cycle. Economists distinguish four phases of the business cycle; the duration and strength of each phase may vary.

Phases of the Business Cycle

Figure 29.1 shows the four phases of a generalized business cycle:

- At a **peak**, such as the middle peak shown in Figure 29.1, business activity has reached a temporary maximum. Here the economy is near or at full employment and the level of real output is at or very close to the economy's capacity. The price level is likely to rise during this phase.
- A **recession** is a period of decline in total output, income, and employment. This downturn, which lasts 6 months or more, is marked by the widespread contraction of business activity in many sectors of the economy. Along with declines in real GDP, significant increases in unemployment occur. Table 29.1 documents the 10 recessions in the United States since 1950.
- In the **trough** of the recession or depression, output and employment “bottom out” at their lowest levels. The trough phase may be either short-lived or quite long.
- A recession is usually followed by a recovery and **expansion**, a period in which real GDP, income, and employment rise. At some point, the economy again approaches full employment. If spending then expands more rapidly than does production capacity, prices of nearly all goods and services will rise. In other words, inflation will occur.

Although business cycles all pass through the same phases, they vary greatly in duration and intensity. Many economists prefer to talk of business “fluctuations” rather than cycles because cycles imply regularity while fluctuations do not. The Great Depression of the 1930s resulted in a 27 percent decline in real GDP over a 3-year period in the United States and seriously impaired business activity for a decade. By comparison, the U.S. recessions detailed in Table 29.1 were less severe in both intensity and duration.

The Business Cycle Dating Committee of the National Bureau of Economic Research (NBER), a nonprofit economic research organization, declares the start and end of recessions in the United States. Citing evidence of declining real output and falling employment, the NBER officially declared that the latest recession began in December 2007. The NBER subsequently declared that the Great Recession ended in June 2009, 18 months after it began. In making this announcement, the NBER pointed out that its declaration was not a forecast for the future path of the economy.

Recessions, of course, occur in other countries, too. For example, nearly all industrial nations and many developing nations have suffered recessions in the past several years.

Causation: A First Glance

The long-run trend of the U.S. economy is expansion and growth. That is why the business cycles in Figure 29.1 are drawn against a trend of economic growth. A key issue in macroeconomics is why the economy sees business cycle fluctuations rather than slow, smooth growth. In terms of Figure 29.1, why does output move up and down rather than just staying on the smooth growth trend line?

Economists have developed several possible explanations. But before turning to them, recall that in Chapter 26 we explained that these theories are founded on the idea that fluctuations are driven by shocks—unexpected events that individuals and firms may have trouble adjusting to. Also recall that short-run price stickiness is widely believed to be a major factor preventing the economy from rapidly adjusting to shocks. With prices sticky in the short run, price changes cannot quickly equalize the quantities demanded of goods

and services with their respective quantities supplied after a shock has happened. Instead, the economy is forced to respond to shocks in the short run primarily through changes in output and employment rather than through changes in prices.

Economists cite several possible general sources of shocks that can cause business cycles.

- **Irregular innovation** Significant new products or production methods, such as those associated with the railroad, automobile, computer, and Internet, can rapidly spread through the economy, sparking sizable increases in investment, consumption, output, and employment. After the economy has largely absorbed the new innovation, the economy may for a time slow down or possibly decline. Because such innovations occur irregularly and unexpectedly, they may contribute to the variability of economic activity.
- **Productivity changes** When productivity—output per unit of input—unexpectedly increases, the economy booms; when productivity unexpectedly decreases, the economy recedes. Such changes in productivity can result from unexpected changes in resource availability (of, say, oil or agricultural commodities) or from unexpected changes in the general rate of technological advance.
- **Monetary factors** Some economists see business cycles as purely monetary phenomena. When a nation’s central bank shocks the economy by creating more money than people were expecting, an inflationary boom in output occurs. By contrast, printing less money than people were expecting triggers an output decline and, eventually, a price-level fall.
- **Political events** Unexpected political events, such as peace treaties, new wars, or the 9/11 terrorist attacks, can create economic opportunities or strains. In adjusting to these shocks, the economy may experience upswings or downswings.
- **Financial instability** Unexpected financial bubbles (rapid asset price increases) or bursts (abrupt asset price decreases) can spill over to the general economy by expanding or contracting lending, and boosting or eroding the confidence of consumers and businesses. Booms and busts in the rest of the economy may follow.

The severe recession of 2007–2009 was precipitated by a combination of excessive money and a financial frenzy that led to overvalued real estate and unsustainable mortgage debt. Institutions bundled this debt into new securities (“derivatives”) that were sold to financial investors. Some of the investors, in turn, bought insurance against losses that might arise from the securities. As real estate prices plummeted and mortgage defaults unexpectedly rocketed, the securitization and insurance structure buckled and nearly collapsed. Credit markets froze, pessimism prevailed, and spending by businesses and households declined.

Whatever the source of economic shocks, most economists agree that the *immediate* cause of the large majority of cyclical changes in the levels of real output and employment is unexpected changes in the level of total spending. If total spending unexpectedly sinks and firms cannot lower prices, firms will find themselves selling fewer units of output (since with prices fixed, a decreased amount of spending implies fewer items purchased). Slower sales will cause firms to cut back on production. As they do, GDP will fall. And because fewer workers will be needed to produce less output, employment also will fall. The economy will contract and enter a recession.

By contrast, if the level of spending unexpectedly rises, output, employment, and incomes will rise. This is true because, with prices sticky, the increased spending will mean that consumers will be buying a larger volume of goods and services (since, with prices fixed, more spending means more items purchased). Firms will respond by increasing output. This will increase GDP. And because firms will need to hire more workers to produce the larger volume of output, employment also will increase. The economy will boom and enjoy an expansion. Eventually, as time passes and prices become more flexible, prices are also likely to rise as a result of the increased spending.

Cyclical Impact: Durables and Nondurables

Although the business cycle is felt everywhere in the economy, it affects different segments in different ways and to different degrees.

Firms and industries producing *capital goods* (for example, housing, commercial buildings, heavy equipment, and farm implements) and *consumer durables* (for example, automobiles, personal computers, and refrigerators) are affected most by the business cycle. Within limits, firms can postpone the purchase of capital goods. For instance, when the economy goes into recession, producers frequently delay the purchase of new equipment and the construction of new plants. The business outlook simply does not warrant increases in the stock of capital goods. In good times, capital goods are usually replaced before they depreciate completely. But when recession strikes, firms patch up their old equipment and make do. As a result, investment in capital goods declines sharply. Firms that have excess plant capacity may not even bother to replace all the capital that is depreciating. For them, net investment may be negative. The pattern is much the same for consumer durables such as automobiles and major appliances. When recession occurs and households must trim their budgets, purchases of these goods are often deferred. Families repair their old cars and appliances rather than buy new ones, and the firms producing these products suffer. (Of course, producers of capital goods and consumer durables also benefit most from expansions.)

In contrast, *service industries* and industries that produce *nondurable consumer goods* are somewhat insulated from the

most severe effects of recession. People find it difficult to cut back on needed medical and legal services, for example. And a recession actually helps some service firms, such as pawnbrokers and law firms that specialize in bankruptcies. Nor are the purchases of many nondurable goods such as food and clothing easy to postpone. The quantity and quality of purchases of nondurables will decline, but not so much as will purchases of capital goods and consumer durables.

QUICK REVIEW 29.1

- ✓ The typical business cycle goes through four phases: peak, recession, trough, and expansion.
- ✓ Fluctuations in output and employment are caused by economic shocks combining with sticky prices.
- ✓ Sources of shocks that cause recessions include irregular innovation, productivity changes, monetary factors, political events, and financial instability.
- ✓ During a recession, industries that produce capital goods and consumer durables normally suffer greater output and employment declines than do service and nondurable consumer goods industries.

Unemployment

LO29.2 Illustrate how unemployment is measured and explain the different types of unemployment.

Two problems that arise over the course of the business cycle are unemployment and inflation. Let's look at unemployment first.

Measurement of Unemployment

The U.S. Bureau of Labor Statistics (BLS) conducts a nationwide random survey of some 60,000 households each month to determine who is employed and who is not employed. In a series of questions, it asks which members of the household are working, unemployed and looking for work, not looking for work, and so on. From the answers, it determines an unemployment rate for the entire nation.

Figure 29.2 helps explain the mathematics. The BLS divides the total U.S. population into three groups. One group is made up of people under 16 years of age and people who are institutionalized, for example, in mental hospitals or correctional institutions. Such people are not considered potential members of the labor force.

A second group, labeled “Not in labor force,” is composed of adults who are potential workers but are not employed and are not seeking work. For example, they are stay-at-home parents, full-time students, or retirees.

The third group is the **labor force**, which constituted slightly more than 50 percent of the total population in 2009. The labor force consists of people who are able and willing to

FIGURE 29.2 The U.S. labor force, employment, and unemployment, 2015.* The labor force consists of persons 16 years of age or older who are not in institutions and who are (1) employed or (2) unemployed but seeking employment.

work. Both those who are employed and those who are unemployed but actively seeking work are counted as being in the labor force. The **unemployment rate** is the percentage of the labor force unemployed:

$$\text{Unemployment rate} = \frac{\text{unemployed}}{\text{labor force}} \times 100$$

The statistics underlying the rounded numbers in Figure 29.2 show that in 2015 the unemployment rate averaged

$$\frac{7,900,000}{157,800,000} \times 100 = 5.0\%$$

Despite the use of scientific sampling and interviewing techniques, the data collected in this survey are subject to criticism:

- **Part-time employment** The BLS lists all part-time workers as fully employed. In 2015 about 30 million people worked part-time as a result of personal choice. But another 6 million part-time workers either wanted to work full-time and could not find suitable full-time work or worked fewer hours because of a temporary slack in consumer demand. These last two groups were,

in effect, partially employed and partially unemployed. By counting them as fully employed, say critics, the official BLS data understate the unemployment rate.

- **Discouraged workers** You must be actively seeking work in order to be counted as unemployed. An unemployed individual who is not actively seeking employment is classified as “not in the labor force.” The problem is that many workers, after unsuccessfully seeking employment for a time, become discouraged and drop out of the labor force. The number of such **discouraged workers** was roughly 664,000 in 2015, up from 396,000 in 2007. By not counting discouraged workers as unemployed, say critics, the official BLS data understate the unemployment problem.

Types of Unemployment

There are three *types* of unemployment: frictional, structural, and cyclical.

Frictional Unemployment At any given time some workers are “between jobs.” Some of them will be moving voluntarily from one job to another. Others will have been fired and will be seeking reemployment. Still others will have been laid off temporarily because of seasonal demand. In addition to those between jobs, many young workers will be searching for their first jobs.

As these unemployed people find jobs or are called back from temporary layoffs, other job seekers and laid-off workers will replace them in the “unemployment pool.” It is important to keep in mind that while the pool itself persists because there are always newly unemployed workers flowing into it, most workers do *not* stay in the unemployment pool for very long. Indeed, when the economy is strong, the majority of unemployed workers find new jobs within a couple of months. One should be careful not to make the mistake of confusing the permanence of the pool itself with the false idea that the pool’s membership is permanent, too. On the other hand, there are workers who do remain unemployed and in the pool for very long periods of time—sometimes for many years. As we discuss the different types of unemployment below, notice that certain types tend to be transitory while others are associated with much longer spells of unemployment.

Economists use the term **frictional unemployment**—consisting of *search unemployment* and *wait unemployment*—for workers who are either searching for jobs or waiting to take jobs in the near future. The word “frictional” implies that the labor market does not operate perfectly and instantaneously (without friction) in matching workers and jobs.

Frictional unemployment is inevitable and, at least in part, desirable. Many workers who are voluntarily between jobs are moving from low-paying, low-productivity jobs to

Downwardly Sticky Wages and Unemployment

Labor markets have an important quirk that helps to explain why unemployment goes up so much during a recession.

The quirk is that wages are flexible upward but sticky downward.

On the one hand, workers are perfectly happy to accept wage increases. So when the economy is booming and firms start bidding for the limited supply of labor, wages rise—often quite rapidly.

On the other hand, workers deeply resent pay cuts. So if the economy goes into a recession and firms need to reduce labor costs, managers almost never cut wages because doing so would only lead to disgruntled employees, low productivity, and—in extreme cases—workers stealing supplies or actively sabotaging their own firms.

Instead, managers usually opt for layoffs. The workers who are let go obviously don’t like being unemployed. But those who remain get to keep their old wages and, consequently, keep on being as productive and cooperative as they were before.

This preference that firms show for layoffs over wage cuts results in downwardly sticky wages and an informal price floor that helps to explain why unemployment goes up so much during a recession. The problem is that when the demand for labor falls during a recession, the informal price floor prevents wages from falling. As a result, there is no way for falling wages to help entice at least some firms to hire a few more workers. Thus, when a recession hits, employment falls more precipitously than it would if wages were downwardly flexible and falling wages could help to increase hiring.

higher-paying, higher-productivity positions. That means greater income for the workers, a better allocation of labor resources, and a larger real GDP for the economy.

Structural Unemployment Frictional unemployment blurs into a category called **structural unemployment**. Here, economists use “structural” in the sense of “compositional.” Changes over time in consumer demand and in technology alter the “structure” of the total demand for labor, both occupationally and geographically.

Occupationally, the demand for certain skills (for example, sewing clothes or working on farms) may decline or even vanish. The demand for other skills (for example, designing software or maintaining computer systems) will intensify. Unemployment results because the composition of the labor force does not respond immediately or completely to the new structure of job opportunities. Workers who find that their skills and experience have become obsolete or unneeded thus find that they have no marketable talents. They are structurally unemployed until they adapt or develop skills that employers want.

Geographically, the demand for labor also changes over time. An example: the migration of industry and thus of employment opportunities from the Snowbelt to the Sunbelt over the past few decades. Another example is the movement of jobs from inner-city factories to suburban industrial parks. And a final example is the so-called *offshoring* of jobs that occurs when the demand for a particular type of labor shifts from domestic firms to foreign firms. As job opportunities shift from one place to another, some workers become structurally unemployed.

The distinction between frictional and structural unemployment is hazy at best. The key difference is that *frictionally* unemployed workers have marketable skills and either live in areas where jobs exist or are able to move to areas where they do. *Structurally* unemployed workers find it hard to obtain new jobs without retraining, gaining additional education, or relocating. Frictional unemployment is short-term; structural unemployment is more likely to be long-term and consequently more serious.

Cyclical Unemployment Unemployment that is caused by a decline in total spending is called **cyclical unemployment** and typically begins in the recession phase of the business cycle. As the demand for goods and services decreases, employment falls and unemployment rises. Cyclical unemployment results from insufficient demand for goods and services. The 25 percent unemployment rate in the depth of the Great Depression in 1933 reflected mainly cyclical unemployment, as did significant parts of the 9.7 percent unemployment rate in 1982, the 7.5 percent rate in 1992, the 5.8 percent rate in 2002, and the 9.3 percent rate in 2009.

Cyclical unemployment is a very serious problem when it occurs. We will say more about its high costs later, but first we need to define “full employment.”

Definition of Full Employment

Because frictional and structural unemployment are largely unavoidable in a dynamic economy, *full employment* is something less than 100 percent employment of the labor force. Economists say that the economy is “fully employed” when it is experiencing only frictional and structural unemployment. That is, full employment occurs when there is no cyclical unemployment.

Economists describe the unemployment rate that is consistent with full employment as the **full-employment rate of unemployment**, or the **natural rate of unemployment (NRU)**. At the NRU, the economy is said to be producing its **potential output**. This is the real GDP that occurs when the economy is “fully employed.”

Note that a fully employed economy does not mean zero unemployment. Even when the economy is fully employed, the NRU is some positive percentage because it takes time for frictionally unemployed job seekers to find open jobs they can fill. Also, it takes time for the structurally unemployed to achieve the skills and geographic relocation needed for reemployment.

“Natural” does not mean, however, that the economy will always operate at this rate and thus realize its potential output. When cyclical unemployment occurs, the economy has much more unemployment than that which would occur at the NRU. Moreover, the economy can operate for a while at an unemployment rate *below* the NRU. At times, the demand for labor may be so great that firms take a stronger initiative to hire and train the structurally unemployed. Also, some parents, teenagers, college students, and retirees who were casually looking for just the right part-time or full-time jobs may quickly find them. Thus the unemployment rate temporarily falls below the natural rate.

Also, the NRU can vary over time as demographic factors, job-search methods, and public policies change. In the 1980s, the NRU was about 6 percent. Today, it is 5 to 6 percent.

Economic Cost of Unemployment

Unemployment that is excessive involves great economic and social costs.

GDP Gap and Okun’s Law The basic economic cost of unemployment is forgone output. When the economy fails to create enough jobs for all who are able and willing to work, potential production of goods and services is irretrievably lost. In terms of Chapter 1’s analysis, unemployment above the natural rate means that society is operating at some point inside its production possibilities curve. Economists call this sacrifice of output a **GDP gap**—the difference between actual and potential GDP. That is:

$$\text{GDP gap} = \text{actual GDP} - \text{potential GDP}$$

The GDP gap can be either negative (actual GDP < potential GDP) or positive (actual GDP > potential GDP). In the case of unemployment above the natural rate, it is negative because actual GDP falls short of potential GDP.

Potential GDP is determined by assuming that the natural rate of unemployment prevails. The growth of potential GDP is simply projected forward on the basis of the economy’s “normal” growth rate of real GDP. Figure 29.3 shows the GDP gap for recent years in the United States. It also

FIGURE 29.3 Actual and potential real GDP and the unemployment rate. (a) The difference between actual and potential GDP is the GDP gap. A negative GDP gap measures the output the economy sacrifices when actual GDP falls short of potential GDP. A positive GDP gap indicates that actual GDP is above potential GDP. (b) A high unemployment rate means a large GDP gap (negative), and a low unemployment rate means a small or even positive GDP gap.

Note that the data for actual real GDP and potential real GDP above differ from the real GDP data in the previous two chapters. The data above are in 2009 dollars, but do not reflect the 2013 redefinition of investment expenditures in the National Income and Product Accounts to include research and development spending.

indicates the close correlation between the actual unemployment rate (Figure 29.3b) and the GDP gap (Figure 29.3a). The higher the unemployment rate, the larger is the GDP gap.

Macroeconomist Arthur Okun was the first to quantify the relationship between the unemployment rate and the GDP gap. **Okun's law** indicates that for every 1 percentage point by which the actual unemployment rate exceeds the natural rate, a negative GDP gap of about 2 percent occurs. With this information, we can calculate the absolute loss of output associated with any above-natural unemployment rate. For example, in 2009 the unemployment rate was 9.3 percent, or 4.3 percentage points above that period's 5.0 percent natural rate of unemployment. Multiplying this 4.3 percent by Okun's 2 indicates that 2009's GDP gap was 8.6 percent of potential GDP (in real terms). By applying this 8.6 percent loss to 2009's potential GDP of \$13,894 billion, we find that the economy sacrificed \$1,195 billion of real output because the natural rate of unemployment was not achieved.

As you can see in Figure 29.3, sometimes the economy's actual output will exceed its potential or full-employment output. Figure 29.3 reveals that an economic expansion in 1999 and 2000, for example, caused actual GDP to exceed potential GDP in those years. There was a positive GDP gap in 1999 and 2000. Actual GDP for a time can exceed potential GDP, but positive GDP gaps create inflationary pressures and cannot be sustained indefinitely.

Unequal Burdens An increase in the unemployment rate from 5 to, say, 9 or 10 percent might be more tolerable to society if every worker's hours of work and wage income were reduced proportionally. But this is not the case. Part of the burden of unemployment is that its cost is unequally distributed.

Table 29.2 examines unemployment rates for various labor market groups for 2 periods. In 2007, the economy achieved full employment, with a 4.6 percent unemployment rate. The economy receded in December 2007 and two years later was feeling the full unemployment impact of the Great Recession. By observing the large variance in unemployment rates for the different groups within each period and comparing the rates between the 2 periods, we can generalize as follows:

- **Occupation** Workers in lower-skilled occupations (for example, laborers) have higher unemployment rates than workers in higher-skilled occupations (for example, professionals). Lower-skilled workers have more and longer spells of structural unemployment than higher-skilled workers. They also are less likely to be self-employed than are higher-skilled workers. Moreover, lower-skilled workers usually bear the brunt of recessions. Manufacturing, construction, and mining

tend to be particularly hard-hit, and businesses generally retain most of their higher-skilled workers, in whom they have invested the expense of training.

- **Age** Teenagers have much higher unemployment rates than adults. Teenagers have lower skill levels, quit their jobs more frequently, are more frequently fired, and have less geographic mobility than adults. Many unemployed teenagers are new in the labor market, searching for their first jobs. Male African-American teenagers, in particular, have very high unemployment rates. The unemployment rate for all teenagers rises during recessions.

- **Race and ethnicity** The unemployment rates for African Americans and Hispanics are higher than that for whites. The causes of the higher rates include lower rates of educational attainment, greater concentration in lower-skilled occupations, and discrimination in the labor market. In general, the unemployment rate for African Americans is twice that of whites and rises by more percentage points than for whites during recessions.
- **Gender** The unemployment rates for men and women normally are very similar. But in the recent recession, the unemployment rate for men significantly exceeded that for women.
- **Education** Less-educated workers, on average, have higher unemployment rates than workers with more education. Less education is usually associated with lower-skilled, less-permanent jobs; more time between jobs; and jobs that are more vulnerable to cyclical layoff.
- **Duration** The number of persons unemployed for long periods—15 weeks or more—as a percentage of the labor force is much lower than the overall unemployment rate. But that percentage rises significantly during recessions. Notice from Table 29.2 that it rose from 1.5 percent of the labor force in 2007 to 4.7 percent in 2009.

Noneconomic Costs

Severe cyclical unemployment is more than an economic malady; it is a social catastrophe. Unemployment means idleness. And idleness means loss of skills, loss of self-respect, plummeting morale, family disintegration, and sociopolitical unrest. Widespread joblessness increases poverty, heightens racial and ethnic tensions, and reduces hope for material advancement.

History demonstrates that severe unemployment can lead to rapid and sometimes violent social and political change. Witness Hitler's ascent to power against a background of unemployment in Germany. Furthermore, relatively high unemployment among some racial and ethnic minorities has contributed to the unrest and violence that has periodically plagued some cities in the United States and abroad. At the individual level, research links increases in suicide, homicide, fatal heart attacks and strokes, and mental illness to high unemployment.

International Comparisons

Unemployment rates differ greatly among nations at any given time. One reason is that nations have different natural rates of unemployment. Another is that nations may be in different phases of their business cycles. Global Perspective 29.1 shows unemployment rates for five industrialized nations for the years 2004 through 2014. Between 2004 and 2008, the U.S. unemployment rate was considerably lower

Compared with Italy, France, and Germany, the United States had a relatively low unemployment rate until the start of the 2007–2009 Great Recession, when the U.S. rate shot up to become the highest among the five nations in 2010 before declining substantially over the next few years while the unemployment rates in Italy and France continued to rise.

than the rates in Italy, France, and Germany. But during the Great Recession, U.S. unemployment spiked to the highest level among the five countries before declining significantly over the following five years.

QUICK REVIEW 29.2

- ✓ Unemployment is of three general types: frictional, structural, and cyclical.
- ✓ The natural unemployment rate (frictional plus structural) is presently 5 to 6 percent in the United States.
- ✓ A positive GDP gap occurs when actual GDP exceeds potential GDP; a negative GDP gap occurs when actual GDP falls short of potential GDP.
- ✓ Society loses real GDP when cyclical unemployment occurs; according to Okun's law, for each 1 percentage point of unemployment above the natural rate, the U.S. economy suffers a 2 percent decline in real GDP below its potential GDP.
- ✓ Lower-skilled workers, teenagers, African Americans and Hispanics, and less-educated workers bear a disproportionate burden of unemployment.

Inflation

L029.3 Explain how inflation is measured and distinguish between cost-push inflation and demand-pull inflation.

We now turn to inflation, another aspect of macroeconomic instability. The problems inflation poses are subtler than those posed by unemployment.

Meaning of Inflation

Inflation is a rise in the general level of prices. When inflation occurs, each dollar of income will buy fewer goods and services than before. Inflation reduces the “purchasing power” of money. But inflation does not mean that *all* prices are rising. Even during periods of rapid inflation, some prices may be relatively constant and others may even fall. For example, although the United States experienced high rates of inflation in the 1970s and early 1980s, the prices of video recorders, digital watches, and personal computers declined.

Measurement of Inflation

The main measure of inflation in the United States is the **Consumer Price Index (CPI)**, compiled by the BLS. The government uses this index to report inflation rates each month and each year. It also uses the CPI to adjust Social Security benefits and income tax brackets for inflation. The CPI reports the price of a “market basket” of some 300 consumer goods and services that are purchased by a typical urban consumer. (The GDP price index of Chapter 27 is a much broader measure of inflation since it includes not only consumer goods and services but also capital goods, goods and services purchased by government, and goods and services that enter world trade.)

The composition of the market basket for the CPI is based on spending patterns of urban consumers in a specific period, presently 2009–2010. The BLS updates the composition of

the market basket every 2 years so that it reflects the most recent patterns of consumer purchases and captures the inflation that consumers are currently experiencing. The BLS arbitrarily sets the CPI equal to 100 for 1982–1984. So the CPI for any particular year is found as follows:

$$\text{CPI} = \frac{\text{price of the most recent market basket in the particular year}}{\text{price estimate of the market basket in 1982–1984}} \times 100$$

The rate of inflation is equal to the percentage growth of CPI from one year to the next. For example, the CPI was 236.7 in 2014, up from 233.0 in 2013. So the rate of inflation for 2014 is calculated as follows:

$$\text{Rate of inflation} = \frac{236.7 - 233.0}{233.0} \times 100 = 1.6\%$$

In rare cases, the CPI declines from one year to the next. For example, the CPI fell from 215.3 in 2008 to 214.5 in 2009. The rate of inflation for 2009 therefore was -0.4 percent. Such price level declines are called **deflation**.

In Chapter 28, we discussed the mathematical approximation called *the rule of 70*, which tells us that we can find the number of years it will take for some measure to double, given its annual percentage increase, by dividing that percentage increase into the number 70. So a 3 percent annual rate of inflation will double the price level in about 23 ($= 70 \div 3$) years. Inflation of 8 percent per year will double the price level in about 9 ($= 70 \div 8$) years.

Facts of Inflation

Figure 29.4 shows December-to-December rates of annual inflation in the United States between 1960 and 2015. Observe that inflation reached double-digit rates in the 1970s and early 1980s but has since declined and has been relatively mild recently.

Inflation rates in the United States in recent years were neither extraordinarily high nor extraordinarily low relative to rates in other industrial nations.

Source: World Economic Outlook Database, April 2016, International Monetary Fund, www.imf.org.

In recent years U.S. inflation has been neither unusually high nor low relative to inflation in several other industrial countries (see Global Perspective 29.2). Some nations (not shown) have had double-digit or even higher annual rates of inflation in recent years. In 2015, for example, the annual inflation rate in Argentina was 28 percent; Yemen, 30 percent; Syria, 34 percent; Ukraine, 49 percent; and Venezuela, 275 percent. Zimbabwe's inflation rate was 14.9 billion percent in 2008 before Zimbabwe reformed its currency the following year.

Types of Inflation

Nearly all prices in the economy are set by supply and demand. Consequently, if the economy is experiencing inflation and the overall level of prices is rising, we need to look for an explanation in terms of supply and demand.

Demand-Pull Inflation Usually, increases in the price level are caused by an excess of total spending beyond the economy's capacity to produce. Where inflation is rapid and sustained, the cause invariably is an overissuance of money by the central bank (the Federal Reserve in the United States). When resources are already fully employed, the business sector cannot respond to excess demand by expanding output. So the excess demand bids up the prices of the limited output,

producing **demand-pull inflation**. The essence of this type of inflation is "too much spending chasing too few goods."

Cost-Push Inflation Inflation also may arise on the supply, or cost, side of the economy. During some periods in U.S. economic history, including the mid-1970s, the price level increased even though total spending was not excessive. These were periods when output and employment were both *declining* (evidence that total spending was not excessive) while the general price level was *rising*.

The theory of **cost-push inflation** explains rising prices in terms of factors that raise **per-unit production costs** at each level of spending. A per-unit production cost is the average cost of a particular level of output. This average cost is found by dividing the total cost of all resource inputs by the amount of output produced. That is,

$$\text{Per-unit production cost} = \frac{\text{total input cost}}{\text{units of output}}$$

Rising per-unit production costs squeeze profits and reduce the amount of output firms are willing to supply at the existing price level. As a result, the economy's supply of goods and services declines and the price level rises. In this scenario, costs are *pushing* the price level upward, whereas in demand-pull inflation demand is *pulling* it upward.

The major source of cost-push inflation has been so-called *supply shocks*. Specifically, abrupt increases in the costs of raw materials or energy inputs have on occasion driven up per-unit production costs and thus product prices. The rocketing prices of imported oil in 1973–1974 and again in 1979–1980 are good illustrations. As energy prices surged upward during these periods, the costs of producing and transporting virtually every product in the economy rose. Cost-push inflation ensued.

Complexities

The real world is more complex than the distinction between demand-pull and cost-push inflation suggests. It is difficult to distinguish between demand-pull inflation and cost-push inflation unless the original source of inflation is known. For example, suppose a significant increase in total spending occurs in a fully employed economy, causing demand-pull inflation. But as the demand-pull stimulus works its way through various product and resource markets, individual firms find their wage costs, material costs, and fuel prices rising. From their perspective they must raise their prices because production costs (someone else's prices) have risen. Although this inflation is clearly demand-pull in origin, it may mistakenly appear to be cost-push inflation to business firms and to government. Without proper identification of the source of the inflation, government and the Federal Reserve may be slow to undertake policies to reduce excessive total spending.

Another complexity is that cost-push inflation and demand-pull inflation differ in their sustainability. Demand-pull inflation will continue as long as there is excess total spending. Cost-push inflation is automatically self-limiting; it will die out by itself. Increased per-unit costs will reduce supply, and this means lower real output and employment. Those decreases will constrain further per-unit cost increases. In other words, cost-push inflation generates a recession. And in a recession, households and businesses concentrate on keeping their resources employed, not on pushing up the prices of those resources.

Clipping Coins

Some interesting early episodes of demand-pull inflation occurred in Europe from the ninth century to the fifteenth century under feudalism. In that

economic system, *lords* (or *princes*) ruled individual fiefdoms and their *vassals* (or *peasants*) worked the fields. The peasants initially paid parts of their harvest as taxes to the princes. Later, when the princes began issuing “coins of the realm,” peasants began paying their taxes with gold coins.

Some princes soon discovered a way to transfer purchasing power from their vassals to themselves without explicitly increasing taxes. As coins came into the treasury, princes clipped off parts of the gold coins, making them slightly smaller. From the clippings they minted new coins and used them to buy more goods for themselves.

This practice of clipping coins was a subtle form of taxation. The quantity of goods being produced in the fiefdom remained the same, but the number of gold coins increased. With “too much money chasing too few goods,” inflation occurred. Each gold coin earned by the peasants therefore had less purchasing power than previously because prices were higher. The increase of the money supply shifted purchasing power away from the peasants and toward the princes just as surely as if the princes had increased taxation of the peasants.

In more recent eras some dictators have simply printed money to buy more goods for themselves, their relatives, and their key loyalists. These dictators, too, have levied hidden taxes on their population by creating inflation.

The moral of the story is quite simple: A society that values price-level stability should not entrust the control of its money supply to people who benefit from inflation.

Core Inflation

Another complication relating to inflation (regardless of type) is noteworthy. Some price-flexible items within the consumer price index—particularly, food and energy—experience rapid changes in supply and demand and therefore considerable price volatility from month to month and year to year. For example, the prices of grain, fruit, vegetables, and livestock sometimes move rapidly in one direction or the other, leading to sizable changes in the prices of food items such as bread, oranges, lettuce, and beef. Also, energy items such as gasoline and natural gas can rise or fall rapidly from period to period. These ups and downs of food and energy prices usually are temporary and often cancel each other out over longer periods.

In tracking inflation, policymakers want to avoid being misled by rapid but temporary price changes that may distort the inflation picture. They mainly are interested in how rapidly the prices of the typically more stable components of the CPI are rising. By stripping volatile food and energy prices from the CPI, policymakers isolate so-called **core inflation**, the underlying increases in the CPI after volatile food and energy prices are removed.

If core inflation is low and stable, policymakers may be satisfied with current policy even though changes in the overall CPI index may be suggesting a rising rate of inflation. But policymakers become greatly concerned when core inflation is high and rising and take deliberate measures to try to halt it. We discuss these policies in later chapters.

QUICK REVIEW 29.3

- ✓ Inflation is a rising general level of prices and is measured as a percentage change in a price index such as the CPI; deflation is a decline in the general level of prices.
- ✓ For the past several years, the U.S. inflation rate has been within the general range of the rates of other advanced industrial nations and far below the rates experienced by some nations.
- ✓ Demand-pull inflation occurs when total spending exceeds the economy's ability to provide goods and services at the existing price level; total spending *pulls* the price level upward.
- ✓ Cost-push inflation occurs when factors such as rapid increases in the prices of imported raw materials drive up per-unit production costs at each level of output; higher costs *push* the price level upward.
- ✓ Core inflation is the underlying inflation rate after volatile food and energy prices have been removed.

Redistribution Effects of Inflation

L029.4 Relate how unanticipated inflation can redistribute real income.

Inflation redistributes real income. This redistribution helps some people and hurts some others while leaving many people largely unaffected. Who gets hurt? Who benefits? Before we can answer, we need some terminology.

Nominal and Real Income

There is a difference between money (or nominal) income and real income. **Nominal income** is the number of dollars received as wages, rent, interest, or profit. **Real income** is a measure of the amount of goods and services nominal income can buy; it is the purchasing power of nominal income, or income adjusted for inflation. That is,

$$\text{Real income} = \frac{\text{nominal income}}{\text{price index (in hundredths)}}$$

Inflation need not alter an economy's overall real income—its total purchasing power. It is evident from the above equation that real income will remain the same when nominal income rises at the same percentage rate as does the price index.

But when inflation occurs, not everyone's nominal income rises at the same pace as the price level. Therein lies the potential for redistribution of real income from some to others. If the change in the price level differs from the change in a person's nominal income, his or her real income will be affected. The following approximation (shown by the \cong sign) tells us roughly how much real income will change:

$$\begin{array}{rcl} \text{Percentage} & \text{percentage} & \text{percentage} \\ \text{change in} & \cong \text{change in} & - \text{change in} \\ \text{real income} & \text{nominal income} & \text{price level} \end{array}$$

For example, suppose that the price level rises by 6 percent in some period. If Bob's nominal income rises by 6 percent, his real income will *remain unchanged*. But if his nominal income instead rises by 10 percent, his real income will *increase* by about 4 percent. And if Bob's nominal income rises by only 2 percent, his real income will *decline* by about 4 percent.¹

¹A more precise calculation uses our equation for real income. In our first illustration above, if nominal income rises by 10 percent from \$100 to \$110 and the price level (index) rises by 6 percent from 100 to 106, then real income has increased as follows:

$$\frac{\$110}{1.06} = \$103.77$$

The 4 percent increase in real income shown by the simple formula in the text is a reasonable approximation of the 3.77 percent yielded by our more precise formula.

Anticipations

The redistribution effects of inflation depend upon whether or not it is expected. We will first discuss situations involving **unanticipated inflation**. As you will see, these cause real income and wealth to be redistributed, harming some and benefiting others. We will then discuss situations involving **anticipated inflation**. These are situations in which people see an inflation coming in advance. With the ability to plan ahead, people are able to avoid or lessen the redistribution effects associated with inflation.

Who Is Hurt by Inflation?

Unanticipated inflation hurts fixed-income recipients, savers, and creditors. It redistributes real income away from them and toward others.

Fixed-Income Receivers People whose incomes are fixed see their real incomes fall when inflation occurs. The classic case is the elderly couple living on a private pension or annuity that provides a fixed amount of nominal income each month. They may have retired in, say, 1993 on what appeared to be an adequate pension. However, by 2009 they would have discovered that inflation had cut the annual purchasing power of that pension—their real income—by one-third.

Similarly, landlords who receive lease payments of fixed dollar amounts will be hurt by inflation as they receive dollars of declining value over time. Likewise, public sector workers whose incomes are dictated by fixed pay schedules may suffer from inflation. The fixed “steps” (the upward yearly increases) in their pay schedules may not keep up with inflation. Minimum-wage workers and families living on fixed welfare incomes also will be hurt by inflation.

Savers Unanticipated inflation hurts savers. As prices rise, the real value, or purchasing power, of an accumulation of savings deteriorates. Paper assets such as savings accounts, insurance policies, and annuities that were once adequate to meet rainy-day contingencies or provide for a comfortable retirement decline in real value during inflation. The simplest case is the person who hoards money as a cash balance. A \$1,000 cash balance would have lost one-third its real value between 1995 and 2015. Of course, most forms of savings earn interest. But the value of savings will still decline if the rate of inflation exceeds the rate of interest.

Example: Suppose that a household saves \$1,000 in a certificate of deposit (CD) in a commercial bank or savings and loan association at 6 percent annual interest. But if inflation is 13 percent (as it was in 1980), the real value or

purchasing power of that \$1,000 will be cut to about \$938 by the end of the year. Although the saver will receive \$1,060 (equal to \$1,000 plus \$60 of interest), deflating that \$1,060 for 13 percent inflation means that its real value is only about \$938 ($= \$1,060 \div 1.13$).

Creditors Unanticipated inflation harms creditors (lenders). Suppose Chase Bank lends Bob \$1,000, to be repaid in 2 years. If in that time the price level doubles, the \$1,000 that Bob repays will have only half the purchasing power of the \$1,000 he borrowed. True, if we ignore interest charges, the same number of dollars will be repaid as was borrowed. But because of inflation, each of those dollars will buy only half as much as it did when the loan was negotiated. As prices go up, the purchasing power of the dollar goes down. So the borrower pays back less-valuable dollars than those received from the lender. The owners of Chase Bank suffer a loss of real income.

Who Is Unaffected or Helped by Inflation?

Some people are unaffected by inflation and others are actually helped by it. For the second group, inflation redistributes real income toward them and away from others.

Flexible-Income Receivers People who have flexible incomes may escape inflation's harm or even benefit from it. For example, individuals who derive their incomes solely from Social Security are largely unaffected by inflation because Social Security payments are *indexed* to the CPI. Benefits automatically increase when the CPI increases, preventing erosion of benefits from inflation. Some union workers also get automatic **cost-of-living adjustments (COLAs)** in their pay when the CPI rises, although such increases rarely equal the full percentage rise in inflation.

Some flexible-income receivers and all borrowers are helped by unanticipated inflation. The strong product demand and labor shortages implied by rapid demand-pull inflation may cause some nominal incomes to spurt ahead of the price level, thereby enhancing real incomes. For some, the 3 percent increase in nominal income that occurs when inflation is 2 percent may become a 7 percent increase when inflation is 5 percent. As an example, property owners faced with an inflation-induced real estate boom may be able to boost rents more rapidly than the rate of inflation. Also, some business owners may benefit from inflation. If product prices rise faster than resource prices, business revenues will increase more rapidly than costs. In those cases, the growth rate of profit incomes will outpace the rate of inflation.

Debtors Unanticipated inflation benefits debtors (borrowers). In our earlier example, Chase Bank's loss of real

income from inflation is Bob's gain of real income. Debtor Bob borrows "dear" dollars but, because of inflation, pays back the principal and interest with "cheap" dollars whose purchasing power has been eroded by inflation. Real income is redistributed away from the owners of Chase Bank toward borrowers such as Bob.

The federal government, which had amassed \$18.2 trillion of public debt through 2015, has also benefited from inflation. Historically, the federal government regularly paid off its loans by taking out new ones. Inflation permitted the Treasury to pay off its loans with dollars of less purchasing power than the dollars originally borrowed. Nominal national income and therefore tax collections rise with inflation; the amount of public debt owed does not. Thus, inflation reduces the real burden of the public debt to the federal government.

Anticipated Inflation

The redistribution effects of inflation are less severe or are eliminated altogether if people anticipate inflation and can adjust their nominal incomes to reflect the expected price-level rises. The prolonged inflation that began in the late 1960s prompted many labor unions in the 1970s to insist on labor contracts with cost-of-living adjustment clauses.

Similarly, if inflation is anticipated, the redistribution of income from lender to borrower may be altered. Suppose a lender (perhaps a commercial bank or a savings and loan institution) and a borrower (a household) both agree that 5 percent is a fair rate of interest on a 1-year loan provided the price level is stable. But assume that inflation has been occurring and is expected to be 6 percent over the next year. If the bank lends the household \$100 at 5 percent interest, the bank will be paid back \$105 at the end of the year. But if 6 percent inflation does occur during that year, the purchasing power of the \$105 will have been reduced to about \$99. The lender will, in effect, have paid the borrower \$1 for the use of the lender's money for a year.

The lender can avoid this subsidy by charging an *inflation premium*—that is, by raising the interest rate by 6 percent, the amount of the anticipated inflation. By charging 11 percent, the lender will receive back \$111 at the end of the year. Adjusted for the 6 percent inflation, that amount will have roughly the purchasing power of \$105 worth of today's money. The result then will be a mutually agreeable transfer of purchasing power from borrower to lender of \$5, or 5 percent, for the use of \$100 for 1 year. Financial institutions have also developed variable-interest-rate mortgages to protect themselves from the adverse effects of inflation. (Incidentally, this example points out that, rather than being a *cause* of inflation, high nominal interest rates are a *consequence* of inflation.)

FIGURE 29.5 The inflation premium and nominal and real interest rates. The inflation premium—the expected rate of inflation—gets built into the nominal interest rate. Here, the nominal interest rate of 11 percent comprises the real interest rate of 5 percent plus the inflation premium of 6 percent.

Our example reveals the difference between the real rate of interest and the nominal rate of interest. The **real interest rate** is the percentage increase in *purchasing power* that the borrower pays the lender. In our example the real interest rate is 5 percent. The **nominal interest rate** is the percentage increase in *money* that the borrower pays the lender, including that resulting from the built-in expectation of inflation, if any. In equation form:

$$\text{Nominal interest rate} = \text{real interest rate} + \text{inflation premium (the expected rate of inflation)}$$

As illustrated in Figure 29.5, the nominal interest rate in our example is 11 percent.

Negative Nominal Interest Rates

In response to slow recoveries after the Great Recession, many nations attempted to stimulate their economies by intentionally forcing the nominal interest rate on short-term loans to become negative. By early 2016, a negative short-term interest rate had been engineered by Denmark, Japan, Switzerland, Sweden, and the 19 European countries that use the euro as their currency.

In terms of the equation illustrated in Figure 29.5, a negative nominal interest rate on the left side of the equals sign implies that the real interest rate and the inflation premium must sum to a number less than zero on the right side of the equals sign. Either the real interest rate or the inflation premium (or both!) have to be negative for the nominal interest rate to be negative.

In the countries where a negative nominal interest rate was imposed, the inflation rate was positive and expected to remain positive. As a result, the inflation premium was

positive. We can therefore conclude that the short-term real interest rate must have been negative (because the only way that the real interest rate and the inflation premium can sum to a negative nominal interest rate when the inflation premium is positive is if the real interest rate is negative).

A negative real interest rate implies that savers lose purchasing power over time. The governments that opted for negative nominal interest rates hoped that this penalty against saving would result in consumers deciding to consume more today rather than lose purchasing power over time by saving. The governments hoped that higher consumption expenditures would boost economic activity.

But a negative real interest rate might also produce the opposite effect and reduce consumption spending. That's because anybody who is saving with a future goal in mind will have to save more today to make up for the negative rates that will erode the future value of any money saved today. Thus, the governments that opted for negative rates may have been shooting themselves in the foot. As this edition went to print, it was unclear whether negative interest rates would actually boost economic activity as intended.

Other Redistribution Issues

We end our discussion of the redistribution effects of inflation by making three final points:

- **Deflation** The effects of unanticipated deflation—declines in the price level—are the reverse of those of inflation. People with fixed nominal incomes will find their real incomes enhanced. Creditors will benefit at the expense of debtors. And savers will discover that the purchasing power of their savings has grown because of the falling prices.
- **Mixed effects** A person who is simultaneously an income earner, a holder of financial assets, and a debtor will probably find that the redistribution impact of unanticipated inflation is cushioned. If the person owns fixed-value monetary assets (savings accounts, bonds, and insurance policies), inflation will lessen their real value. But that same inflation may produce an increase in the person's nominal wage. Also, if the person holds a fixed-interest-rate mortgage, the real burden of that debt will decline. In short, many individuals are simultaneously hurt and helped by inflation. All these effects must be considered before we can conclude that any particular person's net position is better or worse because of inflation.
- **Arbitrariness** The redistribution effects of inflation occur regardless of society's goals and values. Inflation lacks a social conscience and takes from some and gives to others, whether they are rich, poor, young, old, healthy, or infirm.

The Specter of Deflation

Inflation rates typically rise during the expansion phase of the business cycle as demand increases faster than supply throughout the economy. But

when the peak has past and the recession phase of the business cycle begins, the inflation rate will tend to decline as unemployment rises and the demand for goods and services declines. In some cases, the decrease in demand may be so precipitous that deflation (a falling price level) becomes a possibility.

Economists fear deflation because it can lead to a wave of bankruptcies among firms that owe money. When prices fall, firms have a hard time making enough revenue to pay back their loans. They may be selling just as much stuff as before, but will now receive less money for it due to falling prices. That reduction in revenue can lead to bankruptcy. If enough bankruptcies occur, deflation may accelerate as workers are laid off and demand decreases even more. The downward spiral may be further exacerbated if consumers delay purchases in anticipation of lower future prices. After all, why buy something today if its price is expected to be substantially lower in a month?

To prevent the downward spiral of deflation, central banks use monetary policy to try to always maintain a positive inflation rate. They are almost always successful, so that deflation hardly ever takes hold, even after severe recessions like the Great Recession of 2007–2009. That's good news because with inflation always at least a little bit positive, a downward deflationary spiral can't get started.

QUICK REVIEW 29.4

- ✓ Inflation harms those who receive relatively fixed nominal incomes and either leaves unaffected or helps those who receive flexible nominal incomes.
- ✓ Unanticipated inflation hurts savers and creditors while benefiting debtors.
- ✓ The nominal interest rate equals the real interest rate plus the inflation premium (the expected rate of inflation).

Does Inflation Affect Output?

LO29.5 Discuss how inflation may affect the economy's level of real output.

Thus far, our discussion has focused on how inflation redistributes a specific level of total real income. But inflation also

may affect an economy's level of real output (and thus its level of real income). The direction and significance of this effect on output depend on the type of inflation and its severity.

Cost-Push Inflation and Real Output

Recall that abrupt and unexpected rises in key resource prices such as oil can sufficiently drive up overall production costs to cause cost-push inflation. As prices rise, the quantity demanded of goods and services falls. So firms respond by producing less output, and unemployment goes up.

Economic events of the 1970s provide an example of how inflation can reduce real output. In late 1973 the Organization of Petroleum Exporting Countries (OPEC), by exerting its market power, managed to quadruple the price of oil. The cost-push inflationary effects generated rapid price-level increases in the 1973–1975 period. At the same time, the U.S. unemployment rate rose from slightly less than 5 percent in 1973 to 8.5 percent in 1975. Similar outcomes occurred in 1979–1980 in response to a second OPEC oil supply shock.

In short, cost-push inflation reduces real output. It redistributes a decreased level of real income.

Demand-Pull Inflation and Real Output

Economists do not fully agree on the effects of mild inflation (less than 3 percent) on real output. One perspective is that even low levels of inflation reduce real output because inflation diverts time and effort toward activities designed to hedge against inflation. Here are some examples of this:

- Businesses must incur the cost of changing thousands of prices on their shelves and in their computers simply to reflect inflation.
- Households and businesses must spend considerable time and effort obtaining the information they need to distinguish between real and nominal values such as prices, wages, and interest rates.
- To limit the loss of purchasing power from inflation, people try to limit the amount of money they hold in their billfolds and checking accounts at any one time and instead put more money into interest-bearing accounts and stock and bond funds. But cash and checks are needed in even greater amounts to buy the higher-priced goods and services. So more frequent trips, phone calls, or Internet visits to financial institutions are required to transfer funds to checking accounts and billfolds, when needed.

Without inflation, these uses of resources, time, and effort would not be needed, and they could be diverted toward producing more valuable goods and services. Proponents of “zero inflation” bolster their case by pointing to cross-country studies that indicate that lower rates of inflation are associated with higher rates of economic growth. Even mild inflation, say these economists, is detrimental to economic growth.

Employment after the Great Recession

Employment Growth Has Been Slow and Weak Since the Great Recession.

Soon after the Great Recession ended, some economists warned that the economy would grow only very slowly as it came out of the downturn. They pointed out that not all recessions are created equal. Recessions that follow credit (lending) bubbles usually take from between 7 and 15 years to recover from, rather than the 2 or 3 years that is typical for a normal recession. Since the Great Recession had been preceded by history's largest credit bubble, they were expecting very slow growth.

Their worries were well founded. It was slow going not only for GDP growth but also employment growth. Employment peaked at a high of 139.5 million (part-time plus full-time) jobs in November 2007 before falling to a low of 127.8 million jobs in January 2010. It then 4.5 years before the economy was able to once again provide employment to 139.5 million people.

The recovery in overall employment was in some sense illusory, however. The composition of jobs had changed, with millions transitioning from full-time employment to part-time employment as full-time jobs became relatively scarce. The number of full-time employees declined from 121.8 million in December 2007 to 110.5 million in December 2009. At the same time, the number of part-time employees rose from 24.7 million in December 2007 to 27.4 million in December 2009. So 11.3 million full-time jobs were lost while 2.7 million part-time jobs were gained. The gain in part-time work helped to disguise the decline in full-time work because when anybody looked at total employment (the sum of full-time and part-time jobs) the decline was "only" 8.6 million jobs.

Another troubling pattern was that employment growth mostly went to older workers. Between December 2007 and December 2009, the number of jobs held by people age 54 or younger fell by 6.5 percent (from 100.5 million jobs to 94.0 million jobs). By contrast, the number of jobs held by people 55 or older increased by 4.2 percent (from 26.2 million jobs to 27.3 million jobs) over the same time period.

Economists believe that this age-related difference in employment was due to employers favoring experienced workers in tough times. Why hire someone with only 5 years of work experience when you can get someone with 30 years of work experience for the same salary? That sort of thinking may also explain why the recovery period after the Great Recession also favored older workers. The number of older employees increased from 28.2 million to 34.2 million (or by 21.2 percent) between December 2009 and March 2016. By contrast, the number of jobs held by people age 54 or younger

Source: © Ingram Publishing/SuperStock RF

increased from 94.0 million to 98.0 million (or just 4.3 percent) over the same time period. Even worse, the number of jobs for people age 54 and younger was still 2.5 million lower in March 2016 than it had been in December 2007.

The weakness of employment growth after the Great Recession was also evident when looking at the employment-population ratio, which is the percentage of people age 16 or older who have either a full-time job or a part-time job. The employment-population ratio fell from a pre-recession peak of 63.4 percent in December 2006 to a post-recession low of 58.2 percent in November 2010. Recovery in the employment-population ratio was slow and in March 2016 the statistic remained at just 59.9 percent, meaning that the number of occupied jobs relative to the number of people 16 and older was still 3.5 percent less than when the Great Recession began. New jobs were being created, but not quickly enough to keep up with population growth.

These facts should be kept in mind when considering the most commonly referenced employment statistic, the unemployment rate. By March 2016 the unemployment rate had declined to 5.0 percent, the same level it had been at when the Great Recession started in late 2007. If one had only looked at the unemployment rate, one might have concluded that things had returned to normal. But the data on part-time versus full-time jobs, age-related employment growth, and the employment-population ratio indicated that the jobs market was still struggling almost 7 years after the Great Recession ended.

In contrast, other economists point out that full employment and economic growth depend on strong levels of total spending. Such spending creates high profits, strong demand for labor, and a powerful incentive for firms to expand their plants and equipment. In this view, the mild inflation that is a by-product of strong spending is a small price to pay for full employment and continued economic growth.

Moreover, a little inflation may have positive effects because it makes it easier for firms to adjust real wages downward when the demands for their products fall. With mild inflation, firms can reduce real wages by holding nominal wages steady. With zero inflation firms would need to cut nominal wages to reduce real wages. Such cuts in nominal wages are highly visible and may cause considerable worker resistance and labor strife.

Finally, defenders of mild inflation say that it is much better for an economy to err on the side of strong spending, full employment, economic growth, and mild inflation than on the side of weak spending, unemployment, recession, and deflation.

Hyperinflation

All economists agree that **hyperinflation**, which is extraordinarily rapid inflation, can have a devastating impact on real output and employment.

As prices shoot up sharply and unevenly during hyperinflation, people begin to anticipate even more rapid inflation and normal economic relationships are disrupted. Business owners do not know what to charge for their products. Consumers do not know what to pay. Resource suppliers want to be paid with actual output, rather than with rapidly depreciating money. Money eventually becomes almost worthless and ceases to do its job as a medium of exchange. Businesses, anticipating further price increases, may find that hoarding both materials and finished products is profitable. Individual savers may decide to buy non-productive wealth—jewels, gold and other precious metals, real estate, and so forth—rather than providing funds that can be borrowed to purchase capital equipment. The economy may be thrown into a state of barter, and production and exchange drop further. The net result is economic collapse and, often, political chaos.

Examples of hyperinflation are Germany after the First World War and Japan after the Second World War. In Germany, “prices increased so rapidly that waiters changed the prices on the menu several times during the course of a lunch. Sometimes customers had to pay double the price listed on the menu when they ordered.”² In postwar Japan in 1947, “fisherman and farmers . . . used scales to weigh currency and change, rather than bothering to count it.”³

There are also more recent examples: Between June 1986 and March 1991 the cumulative inflation in Nicaragua was 11,895,866,143 percent. From November 1993 to December 1994 the cumulative inflation rate in the Democratic Republic of Congo was 69,502 percent. From February 1993 to January 1994 the cumulative inflation rate in Serbia was 156,312,790 percent.⁴

Such dramatic hyperinflations are always the consequence of highly imprudent expansions of the money supply by government. The rocketing money supply produces frenzied total spending and severe demand-pull inflation. Zimbabwe’s 14.9 billion percent inflation in 2008 is just the latest example.

QUICK REVIEW 29.5

- ✓ Cost-push inflation reduces real output and employment.
- ✓ Economists argue about the effects of demand-pull inflation. Some argue that even mild demand-pull inflation (1 to 3 percent) reduces the economy’s real output. Other say that mild inflation may be a necessary by-product of the high and growing spending that produces high levels of output, full employment, and economic growth.
- ✓ Hyperinflation, caused by highly imprudent expansions of the money supply, may undermine the monetary system and cause severe declines in real output.

SUMMARY

LO29.1 Describe the business cycle and its primary phases.

The United States and other industrial economies have gone through periods of fluctuations in real GDP, employment, and the price level. Although they have certain phases in common—peak,

recession, trough, expansion—business cycles vary greatly in duration and intensity.

Although economists explain the business cycle in terms of underlying causal factors such as major innovations, productivity shocks, money creation, and financial crises, they generally agree

that changes in the level of total spending are the immediate causes of fluctuating real output and employment.

The business cycle affects all sectors of the economy, though in varying ways and degrees. The cycle has greater effects on output and employment in the capital goods and durable consumer goods industries than in the services and nondurable goods industries.

L029.2 Illustrate how unemployment is measured and explain the different types of unemployment.

Economists distinguish between frictional, structural, and cyclical unemployment. The full-employment or natural rate of unemployment, which is made up of frictional and structural unemployment, is currently between 5 and 6 percent. The presence of part-time and discouraged workers makes it difficult to measure unemployment accurately.

The GDP gap, which can be either a positive or a negative value, is found by subtracting potential GDP from actual GDP. The economic cost of unemployment, as measured by the GDP gap, consists of the goods and services forgone by society when its resources are involuntarily idle. Okun's law suggests that every 1-percentage-point increase in unemployment above the natural rate causes an additional 2 percent negative GDP gap.

L029.3 Explain how inflation is measured and distinguish between cost-push inflation and demand-pull inflation.

Inflation is a rise in the general price level and is measured in the United States by the Consumer Price Index (CPI). When inflation occurs, each dollar of income will buy fewer goods and services than before. That is, inflation reduces the purchasing power of money. Deflation is a decline in the general price level.

Unemployment rates and inflation rates vary widely globally. Unemployment rates differ because nations have different natural

rates of unemployment and often are in different phases of their business cycles. Inflation and unemployment rates in the United States recently have been in the middle to low range compared with rates in other industrial nations.

Economists discern both demand-pull and cost-push (supply-side) inflation. Demand-pull inflation results from an excess of total spending relative to the economy's capacity to produce. The main source of cost-push inflation is abrupt and rapid increases in the prices of key resources. These supply shocks push up per-unit production costs and ultimately raise the prices of consumer goods.

L029.4 Relate how unanticipated inflation can redistribute real income.

Unanticipated inflation arbitrarily redistributes real income at the expense of fixed-income receivers, creditors, and savers. If inflation is anticipated, individuals and businesses may be able to take steps to lessen or eliminate adverse redistribution effects.

When inflation is anticipated, lenders add an inflation premium to the interest rate charged on loans. The nominal interest rate thus reflects the real interest rate plus the inflation premium (the expected rate of inflation).

L029.5 Discuss how inflation may affect the economy's level of real output.

Cost-push inflation reduces real output and employment. Proponents of zero inflation argue that even mild demand-pull inflation (1 to 3 percent) reduces the economy's real output. Other economists say that mild inflation may be a necessary by-product of the high and growing spending that produces high levels of output, full employment, and economic growth.

Hyperinflation, caused by highly imprudent expansions of the money supply, may undermine the monetary system and cause severe declines in real output.

PROBLEMS

1. Suppose that a country's annual growth rates were 5, 3, 4, -1 , -2 , 2, 3, 4, 6, and 3 in yearly sequence over a 10-year period. What was the country's trend rate of growth over this period? Which set of years most clearly demonstrates an expansionary phase of the business cycle? Which set of years best illustrates a recessionary phase of the business cycle? **LO29.1**
2. Assume the following data for a country: total population, 500; population under 16 years of age or institutionalized, 120; not in labor force, 150; unemployed, 23; part-time workers looking for full-time jobs, 10. What is the size of the labor force? What is the official unemployment rate? **LO29.2**
3. Suppose that the natural rate of unemployment in a particular year is 5 percent and the actual rate of unemployment is 9 percent. Use Okun's law to determine the size of the GDP gap in percentage-point terms. If the potential GDP is \$500 billion in that year, how much output is being forgone because of cyclical unemployment? **LO29.2**
4. If the CPI was 110 last year and is 121 this year, what is this year's rate of inflation? In contrast, suppose that the CPI was 110 last year and is 108 this year. What is this year's rate of inflation? What term do economists use to describe this second outcome? **LO29.3**
5. How long would it take for the price level to double if inflation persisted at (a) 2 percent per year, (b) 5 percent per year, and (c) 10 percent per year? **LO29.3**
6. If your nominal income rose by 5.3 percent and the price level rose by 3.8 percent in some year, by what percentage would your real income (approximately) increase? If your nominal income rose by 2.8 percent and your real income rose by 1.1 percent in some year, what must have been the (approximate) rate of inflation? **LO29.4**
7. Suppose that the nominal rate of inflation is 4 percent and the inflation premium is 2 percent. What is the real interest rate? Alternatively, assume that the real interest rate is 1 percent and the nominal interest rate is 6 percent. What is the inflation premium? **LO29.4**
8. If the inflation premium is 2 percent and the nominal interest rate is 1 percent, what is the real interest rate? What if the inflation premium is 3 percent while the nominal interest rate is 0.5 percent? **LO29.4**

*Note to the Instructor: If you wish to bypass the aggregate expenditures model (Keynesian cross model) covered in full in Chapter 31, assigning the present chapter will provide a seamless transition to the AD-AS model of Chapter 32 and the chapters beyond. If you want to cover the aggregate expenditures model, this present chapter provides the necessary building blocks.

chapter begins that process by examining the basic relationships that exist between three different pairs of economic aggregates. (Recall that to economists “aggregate” means “total” or “combined.”) Specifically, this chapter looks at the relationships between:

- Income and consumption (and income and saving).
- The interest rate and investment.
- Changes in spending and changes in output.

What explains the trends in consumption (consumer spending) and saving reported in the news? How do changes in interest rates affect investment? How can initial changes in spending ultimately produce multiplied changes in GDP? The basic macroeconomic relationships discussed in this chapter answer these questions.

The Income-Consumption and Income-Saving Relationships

LO30.1 Describe how changes in income affect consumption (and saving).

The other-things-equal relationship between income and consumption is one of the best-established relationships in macroeconomics. In examining that relationship, we are also exploring the relationship between income and saving. Recall that economists define *personal saving* as “not spending” or as

“that part of disposable (after-tax) income not consumed.” Saving (S) equals disposable income (DI) minus consumption (C).

Many factors determine a nation’s levels of consumption and saving, but the most significant is disposable income. Consider some recent historical data for the United States. In Figure 30.1 each dot represents consumption and disposable income for 1 year since 1993. The line C that is loosely fitted to these points shows that consumption is directly (positively) related to disposable income; moreover, households spend most of their income.

But we can say more. The **45°(degree) line** is a reference line. Because it bisects the 90° angle formed by the two axes of the graph, each point on it is equidistant from the two axes. At each point on the 45° line, consumption would equal disposable income, or $C = DI$. Therefore, the vertical distance between the 45° line and any point on the horizontal axis measures either consumption *or* disposable income. If we let it measure disposable income, the vertical distance between it and the consumption line labeled C represents the amount of saving (S) in that year. Saving is the amount by which actual consumption in any year falls short

of the 45° line—($S = DI - C$). For example, in 2005 disposable income was \$9,401 billion and consumption was \$9,158 billion, so saving was \$243 billion. Observe that the vertical distance between the 45° line and line C increases as we move rightward along the horizontal axis and decreases as we move leftward. Like consumption, saving typically varies directly with the level of disposable income. However, that historical pattern broke down somewhat in several years preceding the recession of 2007–2009.

The Consumption Schedule

The dots in Figure 30.1 represent historical data—the actual amounts of DI , C , and S in the United States over a period of years. But because we want to understand how the economy would behave under different possible scenarios, we need a schedule showing the various amounts that households would *plan* to consume at each of the various levels of disposable income that might prevail at some specific time. Columns 1 and 2 of Table 30.1, represented in **Figure 30.2a (Key Graph)**, show the hypothetical consumption schedule that we

The line C , which generalizes the relationship between consumption and disposable income, indicates a direct relationship and shows that households consume most of their after-tax incomes.

require. This **consumption schedule** (or “consumption function”) reflects the direct consumption–disposable income relationship suggested by the data in Figure 30.1, and it is consistent with many household budget studies. In the aggregate, households increase their spending as their disposable income rises and spend a larger proportion of a small disposable income than of a large disposable income.

The Saving Schedule

It is relatively easy to derive a **saving schedule** (or “saving function”). Because saving equals disposable income less consumption ($S = DI - C$), we need only subtract consumption (Table 30.1, column 2) from disposable income (column 1) to find the amount saved (column 3) at each DI. Thus, columns 1 and 3 in Table 30.1 are the saving schedule, represented in Figure 30.2b. The graph shows that there is a direct relationship between saving and DI but that saving is a smaller proportion of a small DI than of a large DI. If households consume a smaller and smaller proportion of DI as DI increases, then they must be saving a larger and larger proportion.

Remembering that at each point on the 45° line consumption equals DI, we see that *dissaving* (consuming in excess of after-tax income) will occur at relatively low DIs. For example, at \$370 billion (row 1, Table 30.1), consumption is \$375 billion. Households can consume more than their current incomes by liquidating (selling for cash) accumulated wealth or by borrowing. Graphically, dissaving is shown as the vertical distance of the consumption schedule above the 45° line or as the vertical distance of the saving schedule

below the horizontal axis. We have marked the dissaving at the \$370 billion level of income in Figure 30.2a and 30.2b. Both vertical distances measure the \$5 billion of dissaving that occurs at \$370 billion of income.

In our example, the **break-even income** is \$390 billion (row 2, Table 30.1). This is the income level at which households plan to consume their entire incomes ($C = DI$). Graphically, the consumption schedule cuts the 45° line, and the saving schedule cuts the horizontal axis (saving is zero) at the break-even income level.

At all higher incomes, households plan to save part of their incomes. Graphically, the vertical distance between the consumption schedule and the 45° line measures this saving (see Figure 30.2a), as does the vertical distance between the saving schedule and the horizontal axis (see Figure 30.2b). For example, at the \$410 billion level of income (row 3, Table 30.1), both these distances indicate \$5 billion of saving.

Average and Marginal Propensities

Columns 4 to 7 in Table 30.1 show additional characteristics of the consumption and saving schedules.

APC and APS The fraction, or percentage, of total income that is consumed is the **average propensity to consume (APC)**. The fraction of total income that is saved is the **average propensity to save (APS)**. That is,

$$\text{APC} = \frac{\text{consumption}}{\text{income}}$$

FIGURE 30.2 Consumption and saving schedules. The two parts of this figure show the income-consumption and income-saving relationships in Table 30.1 graphically. (a) Consumption rises as income increases. Saving is negative (dissaving occurs) when the consumption schedule is above the 45° line, and saving is positive when the consumption schedule is below the 45° line. (b) Like consumption, saving increases as income goes up. The saving schedule is found by subtracting the consumption schedule in the top graph vertically from the 45° line. For these hypothetical data, saving is -\$5 billion at \$370 billion of income, zero at \$390 billion of income, and \$5 billion at \$410 billion of income. Saving is zero where consumption equals disposable income.

QUICK QUIZ FOR FIGURE 30.2

- The slope of the consumption schedule in this figure is 0.75. Thus, the:
 - slope of the saving schedule is 1.33.
 - marginal propensity to consume is 0.75.
 - average propensity to consume is 0.25.
 - slope of the saving schedule is also 0.75.
- In this figure, when consumption is a positive amount, saving:
 - must be a negative amount.
 - must also be a positive amount.
 - can be either a positive or a negative amount.
 - is zero.
- In this figure:
 - the marginal propensity to consume is constant at all levels of income.
 - the marginal propensity to save rises as disposable income rises.
 - consumption is inversely (negatively) related to disposable income.
 - saving is inversely (negatively) related to disposable income.
- When consumption equals disposable income:
 - the marginal propensity to consume is zero.
 - the average propensity to consume is zero.
 - consumption and saving must be equal.
 - saving must be zero.

Answers: 1. b; 2. c; 3. a; 4. d

and

$$\text{APS} = \frac{\text{saving}}{\text{income}}$$

For example, at \$470 billion of income (row 6, Table 30.1), the APC is $\frac{450}{470} = \frac{45}{47}$, or about 0.96 (= 96 percent), while the APS is $\frac{20}{470} = \frac{2}{47}$, or about 0.04 (= 4 percent). Columns 4 and 5 in Table 30.1 show the APC and APS at each of the 10 levels of DI. As implied by our previous discussion, the APC falls as DI increases, while the APS rises as DI goes up.

Because disposable income is either consumed or saved, the fraction of any DI consumed plus the fraction saved (not consumed) must exhaust that income. Mathematically, $\text{APC} + \text{APS} = 1$ at any level of disposable income, as columns 4 and 5 in Table 30.1 illustrate. So if 0.96 of the \$470 billion of income in row 6 is consumed, 0.04 must be saved. That is why $\text{APC} + \text{APS} = 1$.

Global Perspective 30.1 shows APCs for several countries.

MPC and MPS The fact that households consume a certain proportion of a particular total income, for example, $\frac{45}{47}$ of a \$470 billion disposable income, does not guarantee they will consume the same proportion of any *change* in income they might receive. The proportion, or fraction, of any change in income consumed is called the **marginal propensity to consume (MPC)**, “marginal” meaning “extra” or “a change in.” Equivalently, the MPC is the ratio of a change in consumption to a change in the income that caused the consumption change:

$$\text{MPC} = \frac{\text{change in consumption}}{\text{change in income}}$$

Similarly, the fraction of any change in income saved is the **marginal propensity to save (MPS)**. The MPS is the ratio of a change in saving to the change in income that brought it about:

$$\text{MPS} = \frac{\text{change in saving}}{\text{change in income}}$$

If disposable income is \$470 billion (row 6 horizontally in Table 30.1) and household income rises by \$20 billion to \$490 billion (row 7), households will consume $\frac{15}{20}$, or $\frac{3}{4}$, and save $\frac{5}{20}$, or $\frac{1}{4}$, of that increase in income. In other words, the MPC is $\frac{3}{4}$ or 0.75, and the MPS is $\frac{1}{4}$ or 0.25, as shown in columns 6 and 7.

The sum of the MPC and the MPS for any change in disposable income must always be 1. Consuming or saving out of extra income is an either-or proposition; the fraction of any change in income not consumed is, by definition, saved. If 0.75 of extra disposable income is consumed, 0.25 must be

GLOBAL PERSPECTIVE 30.1

Average Propensities to Consume, Selected Nations

There are surprisingly large differences in average propensities to consume (APCs) among nations. In 2014, Canada, the United States, Korea, and the Netherlands in particular had substantially higher APCs, and thus lower APSs, than several other advanced economies.

saved. The fraction consumed (MPC) plus the fraction saved (MPS) must exhaust the whole change in income:

$$\text{MPC} + \text{MPS} = 1$$

In our example, 0.75 plus 0.25 equals 1.

MPC and MPS as Slopes The MPC is the numerical value of the slope of the consumption schedule, and the MPS is the numerical value of the slope of the saving schedule. We know from the appendix to Chapter 1 that the slope of any line is the ratio of the vertical change to the horizontal change occasioned in moving from one point to another on that line.

Figure 30.3 measures the slopes of the consumption and saving lines, using enlarged portions of Figure 30.2a and 30.2b. Observe that consumption changes by \$15 billion (the vertical change) for each \$20 billion change in disposable income (the horizontal change). The slope of the consumption line is thus 0.75 (= \$15/\$20), which is the value of the MPC. Saving changes by \$5 billion (shown as the vertical change) for every \$20 billion change in disposable income (shown as the horizontal change). The slope of the saving line therefore is 0.25 (= \$5/\$20), which is the value of the MPS.

FIGURE 30.3 The marginal propensity to consume and the marginal propensity to save. In the two parts of this figure, the Greek letter delta (Δ) means “the change in.” (a) The MPC is the slope ($\Delta C/\Delta DI$) of the consumption schedule. (b) The MPS is the slope ($\Delta S/\Delta DI$) of the saving schedule.

Nonincome Determinants of Consumption and Saving

LO30.2 List and explain factors other than income that can affect consumption.

The amount of disposable income is the basic determinant of the amounts households will consume and save. But certain determinants other than income might prompt households to consume more or less at each possible level of income and thereby change the locations of the consumption and saving schedules. Those other determinants are wealth, borrowing, expectations, and interest rates.

- **Wealth** A household’s wealth is the dollar amount of all the assets that it owns minus the dollar amount of its liabilities (all the debt that it owes). Households build wealth by saving money out of current income. The point of building wealth is to increase consumption possibilities. The larger the stock of wealth that a household can build up, the larger will be its present and future consumption possibilities.

Events sometimes suddenly boost the value of existing wealth. When this happens, households tend to increase their spending and reduce their saving. This so-called **wealth effect** shifts the consumption schedule upward and the saving schedule downward. They move in response to households taking advantage of the increased consumption possibilities afforded by the sudden increase in wealth. Examples: In the late 1990s, skyrocketing U.S. stock values expanded the value of household wealth by increasing the value of household assets. Predictably, households spent more and saved less. In contrast, a strong “reverse wealth effect” occurred in 2008. Plunging real estate and stock market prices joined together to erase \$11.2 trillion (yes, trillion) of household wealth. Consumers quickly reacted by reducing their consumption spending. The consumption schedule shifted downward.

- **Borrowing** Household borrowing also affects consumption. When a household borrows, it can increase current consumption beyond what would be possible if its spending were limited to its disposable income. By allowing households to spend more, borrowing shifts the current consumption schedule upward.

But note that there is no “free lunch.” While borrowing in the present allows for higher consumption in the present, it necessitates lower consumption in the future when the debts that are incurred due to the borrowing must be repaid. Stated a bit differently, increased borrowing increases debt (liabilities), which in turn reduces household wealth (since $wealth = assets - liabilities$). This reduction in wealth reduces future consumption possibilities in much the same way that a decline in asset values would. But note that the term “reverse wealth effect” is reserved for situations in which wealth unexpectedly changes because asset values unexpectedly change. It is not used to refer to situations such as the one being discussed here where wealth is intentionally reduced by households through borrowing and piling up debt to increase current consumption.

- **Expectations** Household expectations about future prices and income may affect current spending and saving. For example, the expectation of higher prices tomorrow may cause households to buy more today while prices are still low. Thus, the current consumption schedule shifts up and the current saving schedule shifts down. Or expectations of a recession and thus lower income in the future may lead households to reduce consumption and save more today. Their greater present saving will help build wealth that will help them ride out the expected bad times. The consumption schedule therefore will shift down and the saving schedule will shift up.

- **Real interest rates** When real interest rates (those adjusted for inflation) fall, households tend to borrow more, consume more, and save less. A lower interest rate, for example, decreases monthly loan payments and induces consumers to purchase automobiles and other goods bought on credit. A lower interest rate also diminishes the incentive to save because of the reduced interest “payment” to the saver. These effects on consumption and saving, however, are very modest. They mainly shift consumption toward some products (those bought on credit) and away from others. At best, lower interest rates shift the consumption schedule slightly upward and the saving schedule slightly downward. Higher interest rates do the opposite.

Other Important Considerations

There are several additional important points regarding the consumption and saving schedules:

- **Switching to real GDP** When developing macroeconomic models, economists change their focus from the relationship between consumption (and saving) and *disposable income* to the relationship between consumption (and saving) and *real domestic output (real GDP)*. This modification is reflected in Figure 30.4a and 30.4b, where the horizontal axes measure real GDP.
- **Changes along schedules** The movement from one point to another on a consumption schedule (for example, from *a* to *b* on C_0 in Figure 30.4a) is a *change in the amount consumed* and is solely caused by a change in real GDP. On the other hand, an upward or downward shift of the entire schedule, for example, a shift from C_0 to C_1 or C_2 in Figure 30.4a, is a *shift of the consumption schedule* and is caused by changes in any one or more of the *nonincome* determinants of consumption just discussed.

A similar distinction in terminology applies to the saving schedule in Figure 30.4b.

- **Simultaneous shifts** Changes in wealth, expectations, interest rates, and household debt will shift the consumption schedule in one direction and the saving schedule in the opposite direction. If households decide to consume more at each possible level of real GDP, they must save less, and vice versa. (Even when they spend more by borrowing, they are, in effect, reducing their current saving by the amount borrowed since borrowing is, effectively, “negative saving.”) Graphically, if the consumption schedule shifts upward from C_0 to C_1 in Figure 30.4a, the saving schedule shifts downward, from S_0 to S_1 in Figure 30.4b. Similarly, a downward shift of the consumption schedule from C_0 to C_2 means an upward shift of the saving schedule from S_0 to S_2 .

- **Taxation** In contrast, a change in taxes shifts the consumption and saving schedules in the same direction. Taxes are paid partly at the expense of consumption and partly at the expense of saving. So an increase in taxes will reduce both consumption and saving, shifting the consumption schedule in Figure 30.4a and the saving schedule in Figure 30.4b downward. Conversely, households will partly consume and partly save any decrease in taxes. Both the consumption schedule and saving schedule will shift upward.
- **Stability** The consumption and saving schedules usually are relatively stable unless altered by major tax increases or decreases. Their stability may be because consumption-saving decisions are strongly influenced by long-term considerations such as saving to meet emergencies or saving for retirement. It may also be because changes in the nonincome determinants frequently work in opposite directions and therefore may be self-canceling.

FIGURE 30.4 Shifts of the (a) consumption and (b) saving schedules.

Normally, if households consume more at each level of real GDP, they are necessarily saving less. Graphically this means that an upward shift of the consumption schedule (C_0 to C_1) entails a downward shift of the saving schedule (S_0 to S_1). If households consume less at each level of real GDP, they are saving more. A downward shift of the consumption schedule (C_0 to C_2) is reflected in an upward shift of the saving schedule (S_0 to S_2). This pattern breaks down, however, when taxes change; then the consumption and saving schedules move in the *same* direction—opposite to the direction of the tax change.

The Great Recession and the Paradox of Thrift

The Great Recession of 2007–2009 altered the prior consumption and saving behavior in the economy. Concerned about reduced wealth, high debt, and potential job losses, households increased their saving and reduced their consumption at each level of after-tax income (or each level of GDP). In Figure 30.4, this outcome is illustrated as

the downward *shift* of the consumption schedule in the top graph and the upward *shift* of the saving schedule in the lower graph.

This change of behavior illustrates the so-called **paradox of thrift**, which refers to the possibility that a recession can be made worse when households become more thrifty and save in response to the downturn. The paradox of thrift rests on two major ironies. One irony is that saving more is *good* for the economy in the long run, as noted in Chapter 1 and Chapter 26. It finances investment and therefore fuels subsequent economic growth. But saving more can be *bad* for the economy during a recession. Because firms are pessimistic about future sales, the increased saving is not likely to be matched by an equal amount of added investment. The extra saving simply reduces spending on currently produced goods and services. That means that even more businesses suffer, more layoffs occur, and people's incomes decline even more.

The paradox of thrift has a second irony related to the *fallacy of composition* (Chapter 1, Last Word): Households as a group may inadvertently end up saving less when each individual household tries to save more during a recession. This is because each household's attempt to save more implies that it is also attempting to spend less. Across all households, that collective reduction in total spending in the economy creates additional job losses and further drives down total income. The decline in total income reduces the ability of households as a group to save as much as they did before their spending reduction and subsequent income decline.

QUICK REVIEW 30.1

- ✓ Both consumption spending and saving rise when disposable income increases; both fall when disposable income decreases.
- ✓ The average propensity to consume (APC) is the fraction of any specific level of disposable income that is spent on consumer goods; the average propensity to save (APS) is the fraction of any specific level of disposable income that is saved. The APC falls and the APS rises as disposable income increases.
- ✓ The marginal propensity to consume (MPC) is the fraction of a change in disposable income that is consumed and it is the slope of the consumption schedule; the marginal propensity to save (MPS) is the fraction of a change in disposable income that is saved and it is the slope of the saving schedule.
- ✓ Changes in consumer wealth, consumer expectations, interest rates, household debt, and taxes can shift the consumption and saving schedules (as they relate to real GDP).

The Interest-Rate–Investment Relationship

L030.3 Explain how changes in real interest rates affect investment.

In our consideration of major macro relationships, we next turn to the relationship between the real interest rate and investment. Recall that investment consists of expenditures on new plants, capital equipment, machinery, inventories, and so on. The investment decision is a marginal-benefit–marginal-cost decision: The marginal benefit from investment is the expected rate of return businesses hope to realize. The marginal cost is the interest rate that must be paid for borrowed funds. Businesses will invest in all projects for which the expected rate of return exceeds the interest rate. Expected returns (profits) and the interest rate therefore are the two basic determinants of investment spending.

Expected Rate of Return

Investment spending is guided by the profit motive; businesses buy capital goods only when they think such purchases will be profitable. Suppose the owner of a small cabinetmaking shop is considering whether to invest in a new sanding machine that costs \$1,000 and has a useful life of only 1 year. (Extending the life of the machine beyond 1 year complicates the economic decision but does not change the fundamental analysis. We discuss the valuation of returns beyond 1 year in Chapter 37.) The new machine will increase the firm's output and sales revenue. Suppose the net expected revenue from the machine (that is,

after such operating costs as power, lumber, labor, and certain taxes have been subtracted) is \$1,100. Then, after the \$1,000 cost of the machine is subtracted from the net expected revenue of \$1,100, the firm will have an expected profit of \$100. Dividing this \$100 profit by the \$1,000 cost of the machine, we find that the **expected rate of return**, r , on the machine is 10 percent ($= \$100/\$1,000$). It is important to note that this is an *expected* rate of return, not a *guaranteed* rate of return. The investment may or may not generate as much revenue or as much profit as anticipated. Investment involves risk.

The Real Interest Rate

One important cost associated with investing that our example has ignored is interest, which is the financial cost of borrowing the \$1,000 of *money* “capital” to purchase the \$1,000 of *real* capital (the sanding machine).

The interest cost of the investment is computed by multiplying the interest rate, i , by the \$1,000 borrowed to buy the machine. If the interest rate is, say, 7 percent, the total interest cost will be \$70. This compares favorably with the net expected return of \$100, which produced the 10 percent expected rate of return. If the investment works out as expected, it will add \$30 to the firm’s profit.

We can generalize as follows: If the expected rate of return (10 percent) exceeds the interest rate (here, 7 percent), the investment should be undertaken. The firm expects the investment to be profitable. But if the interest rate (say, 12 percent) exceeds the expected rate of return (10 percent), the investment should not be undertaken. The firm expects the investment to be unprofitable. The firm should undertake all investment projects it thinks will be profitable. This means that the firm should array its prospective investment projects from the highest expected rate of return, r , downward and then invest in all projects for which r exceeds i . The firm therefore should invest to the point where $r = i$ because then it will have undertaken all investments for which r is greater than i .

This guideline applies even if a firm finances the investment internally out of funds saved from past profit rather than borrowing the funds. The role of the interest rate in the investment decision does not change. When the firm uses money from savings to invest in the sander, it incurs an opportunity cost because it forgoes the interest income it could have earned by lending the funds to someone else. That interest cost, converted to percentage terms, needs to be weighed against the expected rate of return.

The *real* rate of interest, rather than the *nominal* rate, is crucial in making investment decisions. Recall from Chapter 29 that the nominal interest rate is expressed in dollars of current value, while the real interest rate is stated in dollars of constant or inflation-adjusted value. Recall that the real interest rate is the nominal rate less the rate of inflation. In our sanding machine illustration, our implicit assumption of a

constant price level ensures that all our data, including the interest rate, are in real terms.

But what if inflation *is* occurring? Suppose a \$1,000 investment is expected to yield a real (inflation-adjusted) rate of return of 10 percent and the nominal interest rate is 15 percent. At first, we would say the investment would be unprofitable. But assume there is ongoing inflation of 10 percent per year. This means the investing firm will pay back dollars with approximately 10 percent less in purchasing power. While the nominal interest rate is 15 percent, the real rate is only 5 percent ($= 15 \text{ percent} - 10 \text{ percent}$). By comparing this 5 percent real interest rate with the 10 percent expected real rate of return, we find that the investment is potentially profitable and should be undertaken.

Investment Demand Curve

We now move from a single firm’s investment decision to total demand for investment goods by the entire business sector. Assume that every firm has estimated the expected rates of return from all investment projects and has recorded those data. We can cumulate (successively sum) these data by asking: How many dollars’ worth of investment projects have an expected rate of return of, say, 16 percent or more? How many have 14 percent or more? How many have 12 percent or more? And so on.

Suppose no prospective investments yield an expected return of 16 percent or more. But suppose there are \$5 billion of investment opportunities with expected rates of return between 14 and 16 percent; an additional \$5 billion yielding between 12 and 14 percent; still an additional \$5 billion yielding between 10 and 12 percent; and an additional \$5 billion in each successive 2 percent range of yield down to and including the 0 to 2 percent range.

To cumulate these figures for each rate of return, r , we add the amounts of investment that will yield each particular rate of return r or higher. This provides the data in the table in **Figure 30.5 (Key Graph)**. The data are shown graphically in Figure 30.5. In the table, the number opposite 12 percent, for example, means there are \$10 billion of investment opportunities that will yield an expected rate of return of 12 percent or more. The \$10 billion includes the \$5 billion of investment expected to yield a return of 14 percent or more plus the \$5 billion expected to yield between 12 and 14 percent.

We know from our example of the sanding machine that an investment project will be undertaken if its expected rate of return, r , exceeds the real interest rate, i . Let’s first suppose i is 12 percent. Businesses will undertake all investments for which r exceeds 12 percent. That is, they will invest until the 12 percent rate of return equals the 12 percent interest rate. Figure 30.5 reveals that \$10 billion of investment spending will be undertaken at a 12 percent interest rate; that means \$10 billion of investment projects have an expected rate of return of 12 percent or more.

FIGURE 30.5 The investment demand curve. The investment demand curve is constructed by arraying all potential investment projects in descending order of their expected rates of return. The curve slopes downward, reflecting an inverse relationship between the real interest rate (the financial “price” of each dollar of investing) and the quantity of investment demanded.

QUICK QUIZ FOR FIGURE 30.5

- The investment demand curve:
 - reflects a direct (positive) relationship between the real interest rate and investment.
 - reflects an inverse (negative) relationship between the real interest rate and investment.
 - shifts to the right when the real interest rate rises.
 - shifts to the left when the real interest rate rises.
- In this figure:
 - greater cumulative amounts of investment are associated with lower real interest rates.
 - lesser cumulative amounts of investment are associated with lower expected rates of return on investment.
 - higher interest rates are associated with higher expected rates of return on investment, and therefore greater amounts of investment.
 - interest rates and investment move in the same direction.
- In this figure, if the real interest rate falls from 6 to 4 percent:
 - investment will increase from 0 to \$30 billion.
 - investment will decrease by \$5 billion.
 - the expected rate of return will rise by 5 percent.
 - investment will increase from \$25 billion to \$30 billion.
- In this figure, investment will be:
 - zero if the real interest rate is zero.
 - \$40 billion if the real interest rate is 16 percent.
 - \$30 billion if the real interest rate is 4 percent.
 - \$20 billion if the real interest rate is 12 percent.

Answers: 1. b; 2. a; 3. d; 4. c

Put another way: At a financial “price” of 12 percent, \$10 billion of investment goods will be demanded. If the interest rate is lower, say, 8 percent, the amount of investment for which r equals or exceeds i is \$20 billion. Thus, firms will demand \$20 billion of investment goods at an 8 percent real interest rate. At 6 percent, they will demand \$25 billion of investment goods.

By applying the marginal-benefit–marginal-cost rule that investment projects should be undertaken up to the point where $r = i$, we see that we can add the real interest rate to the vertical axis in Figure 30.5. The curve in Figure 30.5 not only shows rates of return; it shows the quantity of investment

demanded at each “price” i (interest rate) of investment. The vertical axis in Figure 30.5 shows the various possible real interest rates, and the horizontal axis shows the corresponding quantities of investment demanded. The inverse (downsloping) relationship between the interest rate (price) and dollar quantity of investment demanded conforms to the law of demand discussed in Chapter 3. The curve ID in Figure 30.5 is the economy’s **investment demand curve**. It shows the amount of investment forthcoming at each real interest rate. The level of investment depends on the expected rate of return and the real interest rate.

Shifts of the Investment Demand Curve

LO30.4 Identify and explain factors other than the real interest rate that can affect investment.

Figure 30.5 shows the relationship between the interest rate and the amount of investment demanded, other things equal. When other things change, the investment demand curve shifts. In general, any factor that leads businesses collectively to expect greater rates of return on their investments increases investment demand. That factor shifts the investment demand curve to the right, as from ID_0 to ID_1 in Figure 30.6. Any factor that leads businesses collectively to expect lower rates of return on their investments shifts the curve to the left, as from ID_0 to ID_2 . What are those non-interest-rate determinants of investment demand?

- **Acquisition, maintenance, and operating costs** The initial costs of capital goods, and the estimated costs of operating and maintaining those goods, affect the expected rate of return on investment. When these costs rise, the expected rate of return from prospective investment projects falls and the investment demand curve shifts to the left. Example: Higher electricity costs associated with operating tools and machinery shifts the investment demand curve to the left. Lower costs, in contrast, shift it to the right.
- **Business taxes** When government is considered, firms look to expected returns *after taxes* in making their investment decisions. An increase in business taxes lowers the expected profitability of investments and shifts the investment demand curve to the left; a reduction of business taxes shifts it to the right.

FIGURE 30.6 Shifts of the investment demand curve. Increases in investment demand are shown as rightward shifts of the investment demand curve; decreases in investment demand are shown as leftward shifts of the investment demand curve.

- **Technological change** Technological progress—the development of new products, improvements in existing products, and the creation of new machinery and production processes—stimulates investment. The development of a more efficient machine, for example, lowers production costs or improves product quality and increases the expected rate of return from investing in the machine. Profitable new products (cholesterol medications, Internet services, high-definition televisions, cellular phones, and so on) induce a flurry of investment as businesses tool up for expanded production. A rapid rate of technological progress shifts the investment demand curve to the right.
- **Stock of capital goods on hand** The stock of capital goods on hand, relative to output and sales, influences investment decisions by firms. When the economy is overstocked with production facilities and when firms have excessive inventories of finished goods, the expected rate of return on new investment declines. Firms with excess production capacity have little incentive to invest in new capital. Therefore, less investment is forthcoming at each real interest rate; the investment demand curve shifts leftward.

When the economy is understocked with production facilities and when firms are selling their output as fast as they can produce it, the expected rate of return on new investment increases and the investment demand curve shifts rightward.

- **Planned inventory changes** Recall from Chapter 27 that the definition of investment includes changes in inventories of unsold goods. An increase in inventories is counted as positive investment while a decrease in inventories is counted as negative investment. It is important to remember that some inventory changes are planned, while others are unplanned. Since the investment demand curve deals only with *planned* investment, it is only affected by *planned* changes that firms desire to make to their inventory levels. If firms are planning to increase their inventories, the investment demand curve shifts to the right. If firms are planning on decreasing their inventories, the investment demand curve shifts to the left.

Firms make planned changes to their inventory levels mostly because they are expecting either faster or slower sales. A firm that expects its sales to double in the next year will want to keep more inventory in stock, thereby increasing its investment demand. By contrast, a firm that is expecting slower sales will plan on reducing its inventory, thereby reducing its overall investment demand. But because life often does not turn out as expected, firms often find that the actual amount of inventory investment that they end up making is either more or less than what they had planned. The size of the

gap is, naturally, the dollar amount of their *unplanned* inventory changes. These unplanned inventory adjustments will play a large role in the aggregate expenditures model studied in Chapter 31.

- **Expectations** We noted that business investment is based on expected returns (expected additions to profit). Most capital goods are durable, with a life expectancy of 10 or 20 years. Thus, the expected rate of return on capital investment depends on the firm's expectations of future sales, future operating costs, and future profitability of the product that the capital helps produce. These expectations are based on forecasts of future business conditions as well as on such elusive and difficult-to-predict factors as changes in the domestic political climate, international relations, population growth, and consumer tastes. If executives become more optimistic about future sales, costs, and profits, the investment demand curve will shift to the right; a pessimistic outlook will shift the curve to the left.

Global Perspective 30.2 compares investment spending relative to GDP for several nations in a recent year. Domestic real interest rates and investment demand determine the levels of investment relative to GDP.

Instability of Investment

In contrast to consumption, investment is unstable; it rises and falls quite often. Investment, in fact, is the most volatile component of total spending—so much so that most of the fluctuations in output and employment that happen over the

course of the business cycle can be attributed to demand shocks relating to unexpected increases and decreases in investment. Figure 30.7 shows just how volatile investment in the United States has been. Notice that the percentage swings in investment in real terms are greater than the percentage

The Great Recession and the Investment Riddle

During the severe recession of 2007–2009, real interest rates essentially declined to zero. Figure 30.5 suggests that this drop in interest rates should have boosted investment spending. But investment declined substantially during this period. On an annual basis, it declined by 9 percent in 2008 and 26 percent in 2009. Does this combination of lower real interest rates and reduced investment make Figure 30.5 irrelevant?

Definitely not! The key to the investment riddle is that during the recession, the investment demand curve shifted inward, as from ID_0 to ID_2 in Figure 30.6. This inward shift overwhelmed any investment-increasing effects of the decline of real interest rates. The net result turned out to be less investment, not more.

The leftward shift of the investment demand reflected a decline in the expected returns from investment. Firms envisioned zero or negative returns on investment in new capital because they were facing an overstock of existing capital relative to their current sales. Understandably, they therefore were not inclined to invest. Also, firms were extremely pessimistic about when the economy would regain its strength. This pessimism also contributed to low expected rates of return on investment and thus to exceptionally weak investment demand. Further, even though the interest rate was so low, firms that wanted to borrow and invest found that lenders were reluctant to lend them money for fear that they would not be able to pay back the loans.

swings in real GDP. Several interrelated factors drawn from our previous discussion explain the variability of investment.

- **Variability of expectations** Business expectations can change quickly when some event suggests a significant possible change in future business conditions. Changes in exchange rates, trade barriers, legislative actions, stock market prices, government economic policies, the outlook for war or peace, court decisions in key labor or antitrust cases, and a host of similar considerations may cause substantial shifts in business expectations.
- **Durability** Because of their durability, capital goods have indefinite useful lifespans. Within limits, purchases of capital goods are discretionary and therefore can be postponed. Firms can scrap or replace older equipment and buildings, or they can patch them up and use them for a few more years. Optimism about the future may prompt firms to replace their older facilities and such modernizing will call for a high level of investment.

A less optimistic view, however, may lead to smaller amounts of investment as firms repair older facilities and keep them in use.

- **Irregularity of innovation** New products and processes stimulate investment. Major innovations such as railroads, electricity, airplanes, automobiles, computers, the Internet, and cell phones induce vast upsurges or “waves” of investment spending that in time recede. But such innovations occur quite irregularly, adding to the volatility of investment.
- **Variability of profits** High current profits often generate optimism about the future profitability of new investments, whereas low current profits or losses spawn considerable doubt about the wisdom of new investments. Additionally, firms often save a portion of current profits as retained earnings and use these funds (as well as borrowed funds) to finance new investments. So current profits affect both the incentive and ability to invest. But profits themselves are highly variable from year to year, contributing to the volatility of investment.

In terms of our previous analysis, we would represent volatility of investment as occasional and substantial unexpected shifts of the investment demand curve (as in Figure 30.6), which cause significant changes in investment spending (as in Figure 30.7). These demand shocks can contribute to cyclical instability.

The Multiplier Effect*

L030.5 Illustrate how changes in investment (or one of the other components of total spending) can increase or decrease real GDP by a multiple amount.

A final basic relationship that requires discussion is the relationship between changes in spending and changes in real GDP. Assuming that the economy has room to expand—so that increases

*Instructors who cover the full aggregate expenditures (AE) model (Chapter 31) rather than moving directly to aggregate demand and aggregate supply (Chapter 32) may choose to defer this discussion until after the analysis of equilibrium real GDP.

in spending do not lead to increases in prices—there is a direct relationship between these two aggregates. More spending results in a higher GDP; less spending results in a lower GDP. But there is much more to this relationship. A change in spending, say, investment, ultimately changes output and income by more than the initial change in investment spending. That surprising result is called the *multiplier effect*: a change in a component of total spending leads to a larger change in GDP. The **multiplier** determines how much larger that change will be; it is the ratio of a change in GDP to the initial change in spending (in this case, investment). Stated generally,

$$\text{Multiplier} = \frac{\text{change in real GDP}}{\text{initial change in spending}}$$

By rearranging this equation, we can also say that Change in GDP = multiplier \times initial change in spending.

So if investment in an economy rises by \$30 billion and GDP increases by \$90 billion as a result, we then know from our first equation that the multiplier is 3 (= \$90/\$30).

Note these three points about the multiplier:

- The “initial change in spending” is usually associated with investment spending because of investment’s volatility. But changes in consumption (unrelated to changes in income), net exports, and government purchases also lead to the multiplier effect.
- The “initial change in spending” associated with investment spending results from a change in the real interest rate and/or a shift of the investment demand curve.
- Implicit in the preceding point is that the multiplier works in both directions. An increase in initial spending will create a multiple increase in GDP, while a decrease in spending will create a multiple decrease in GDP.

Rationale

The multiplier effect follows from two facts. First, the economy supports repetitive, continuous flows of expenditures and income through which dollars spent by Smith are received as income by Chin and then spent by Chin and received as income by Gonzales, and so on. (This chapter’s Last Word presents this idea in a humorous way.) Second, any change in income will change both consumption and saving in the same direction as, and by a fraction of, the change in income.

It follows that an initial change in spending will set off a spending chain throughout the economy. That chain of spending, although of diminishing importance at each successive step, will cumulate to a multiple change in GDP. Initial changes in spending produce magnified changes in output and income.

The table in Figure 30.8 illustrates the rationale underlying the multiplier effect. Suppose that a \$5 billion increase in investment spending occurs. We assume that the MPC is 0.75, the MPS is 0.25, and prices remain constant. That is,

neither the initial increase in spending nor any of the subsequent increases in spending will cause prices to rise.

The initial \$5 billion increase in investment generates an equal amount of wage, rent, interest, and profit income because spending and receiving income are two sides of the same transaction. How much consumption will be induced by this \$5 billion increase in the incomes of households? We find the answer by applying the marginal propensity to consume of 0.75 to this change in income. Thus, the \$5 billion increase in income initially raises consumption by \$3.75 (= 0.75 \times \$5) billion and saving by \$1.25 (= 0.25 \times \$5) billion, as shown in columns 2 and 3 in the table.

Other households receive as income (second round) the \$3.75 billion of consumption spending. Those households consume 0.75 of this \$3.75 billion, or \$2.81 billion, and save 0.25 of it, or \$0.94 billion. The \$2.81 billion that is consumed flows to still other households as income to be spent or saved (third round). And the process continues, with the added consumption and income becoming less in each round. The process ends when there is no more additional income to spend.

The bar chart in Figure 30.8 shows several rounds of the multiplier process of the table graphically. As shown by rounds 1 to 5, each round adds a smaller and smaller blue block to national income and GDP. The process, of course, continues beyond the five rounds shown (for convenience we have simply cumulated the subsequent declining blocks into a single block labeled “All other”). The accumulation of the additional income in each round—the sum of the blue blocks—is the total change in income or GDP resulting from the initial \$5 billion change in spending. Because the spending and respending effects of the increase in investment diminish with each successive round of spending, the cumulative increase in output and income eventually ends. In this case, the ending occurs when \$20 billion of additional income accumulates. Thus, the multiplier is 4 (= \$20 billion/\$5 billion).

The Multiplier and the Marginal Propensities

You may have sensed from the table in Figure 30.8 that the fractions of an increase in income consumed (MPC) and saved (MPS) determine the cumulative respending effects of any initial change in spending and therefore determine the size of the multiplier. The MPC and the multiplier are directly related and the MPS and the multiplier are inversely related. The precise formulas are as shown in the next two equations:

$$\text{Multiplier} = \frac{1}{1 - \text{MPC}}$$

Recall, too, that MPC + MPS = 1. Therefore MPS = 1 – MPC, which means we can also write the multiplier formula as

$$\text{Multiplier} = \frac{1}{\text{MPC}}$$

	(1) Change in Income	(2) Change in Consumption (MPC = 0.75)	(3) Change in Saving (MPS = 0.25)
Increase in investment of \$5.00	\$5.00	\$3.75	\$1.25
Second round	3.75	2.81	0.94
Third round	2.81	2.11	0.70
Fourth round	2.11	1.58	0.53
Fifth round	1.58	1.19	0.39
All other rounds	4.75	3.56	1.19
Total	\$20.00	\$15.00	\$5.00

FIGURE 30.8 The multiplier process (MPC = 0.75). An initial change in investment spending of \$5 billion creates an equal \$5 billion of new income in round 1. Households spend \$3.75 (= 0.75 × \$5) billion of this new income, creating \$3.75 billion of added income in round 2. Of this \$3.75 billion of new income, households spend \$2.81 (= 0.75 × \$3.75) billion, and income rises by that amount in round 3. Such income increments over the entire process get successively smaller but eventually produce a total change of income and GDP of \$20 billion. The multiplier therefore is 4 (= \$20 billion/\$5 billion).

This latter formula is a quick way to determine the multiplier. All you need to know is the MPS.

The smaller the fraction of any change in income saved, the greater the respending at each round and, therefore, the greater the multiplier. When the MPS is 0.25, as in our example, the multiplier is 4. If the MPS were 0.2, the multiplier would be 5. If the MPS were 0.33, the multiplier would be 3. Let's see why.

Suppose the MPS is 0.2 and businesses increase investment by \$5 billion. In the first round of the table in Figure 30.8, consumption will rise by \$4 billion (= MPC of 0.8 × \$5 billion) rather than by \$3.75 billion because saving will increase by \$1 billion (= MPS of 0.2 × \$5 billion) rather than \$1.25 billion. The greater rise in consumption in round 1 will produce a greater increase in income in round 2. The same will be true for all successive rounds. If we worked through all rounds of the multiplier, we would find that the process ends when income has cumulatively increased by \$25 billion, not the \$20 billion shown in the table. When the MPS is 0.2 rather than 0.25, the multiplier is 5 (= \$25 billion/\$5 billion) as opposed to 4 (= \$20 billion/\$5 billion).

If the MPS were 0.33 rather than 0.25, the successive increases in consumption and income would be less than those in the table in Figure 30.8. We would discover that the process ended with a \$15 billion increase in income rather than the \$20 billion shown. When the MPS is 0.33, the multiplier is 3 (= \$15 billion/\$5 billion). The mathematics works such that the multiplier is equal to the reciprocal of the MPS. The reciprocal of any number is the quotient you obtain by dividing 1 by that number.

A large MPC (small MPS) means the succeeding rounds of consumption spending shown in Figure 30.8 diminish slowly and thereby cumulate to a large change in income. Conversely, a small MPC (a large MPS) causes the increases in consumption to decline quickly, so the cumulative change in income is small. The relationship between the MPC (and thus the MPS) and the multiplier is summarized in Figure 30.9.

How Large Is the Actual Multiplier Effect?

The multiplier we have just described is based on simplifying assumptions. Consumption of domestic output rises by the

A Humorous Look at the Multiplier

CLEVELAND—Yesterday, the local economy was plunged into a recession in less than 6 hours.

Many people are trying to explain the sudden change in local prospects. Here's one conjecture.

At precisely 9 a.m., Humbug, the Ford dealer, called Mr. Ajani, of Ajani's Men's Wear. "It's a great day, Mr. Ajani! The new models are in. Per your request, I've put in an order for you."

Agitated, Mr. Ajani responded, "That's not going to work Mr. Humbug. I just got hit with an unexpected tax bill. It's huge and I can't afford a new car right now. Sorry."

Humbug hung up. Two minutes later, his cell phone rang.

Source: © Tim Boyle/Getty Images

"This is Tanaka the landscaper. When do you want us to start working on your yard?"

"I'm sorry, Tanaka, but I can't do that right now," said Humbug.

Perplexed, Tanaka responded, "You were so excited about your new yard. What happened?"

"It's one of my customers. He canceled an order because he got hit with an unexpected tax bill."

Two hours later, Tanaka received a call from his wife, Samantha. "I'm so excited! Goldman's Electronics just received our new TV. They said they can install it tomorrow."

"We're going to have to send it back."

FIGURE 30.9 The MPC and the multiplier. The larger the MPC (the smaller the MPS), the greater the size of the multiplier.

increases in income minus the increases in saving. But in reality, consumption of domestic output increases in each round by a lesser amount than implied by the MPS alone. In addition to saving, households use some of the extra income in each round to purchase additional goods from abroad (imports) and pay additional taxes. Buying imports and paying taxes drains off some of the additional consumption spending (on domestic output) created by the increases in income. So the multiplier effect is reduced and the $1/\text{MPS}$ formula for the multiplier overstates the actual outcome. To correct that problem, we would need to change the multiplier equation to

read "1 divided by the fraction of the change in income that is not spent on domestic output." Also, we will find in later chapters that an increase in spending may be partly dissipated as inflation rather than realized fully as an increase in real GDP. This happens when increases in spending drive up prices. The multiplier process still happens, but it induces a much smaller change in real output because, at higher prices, any given amount of spending buys less real output. Economists disagree on the size of the actual multiplier in the United States. Estimates range from as high as 2.5 to as low as zero. So keep in mind throughout later discussions that the actual multiplier is much lower than the multipliers in our simple explanatory examples.

QUICK REVIEW 30.3

- ✓ The multiplier effect reveals that an initial change in spending can cause a larger change in domestic income and output. The multiplier is the factor by which the initial change is magnified: multiplier = change in real GDP/initial change in spending.
- ✓ The higher the marginal propensity to consume (the lower the marginal propensity to save), the larger the multiplier: multiplier = $1/(1 - \text{MPC})$ or $1/\text{MPS}$.
- ✓ Economists disagree on the size of the actual multiplier in the U.S. economy; estimates range all the way from zero to 2.5.

“Why?”

“Because Humbug isn’t going to have that yard put in now that his customer Ajani can’t buy a new car due to an unexpected tax assessment.”

Ten minutes later, Samantha called Goldman’s Electronics. “We don’t need the TV.”

Goldman frowned. He immediately called his travel agent, Gonzales. “Remember that trip to Spain that you scheduled for me?”

“Yes, everything is ready to go. We just need to run your credit card.”

“It’s impossible now. Mrs. Tanaka just sent back an entertainment center because Humbug didn’t sell a car to Ajani because Ajani can’t figure out how to pay his taxes.”

Gonzalez got online and canceled Goldman’s trip to Spain. He also went over to his local bank to talk to the lending officer, Tommy Tightfist. “I can’t make this month’s loan payment because Goldman canceled his trip to Spain.”

Tightfist got upset. When Kozysic the baker came into the bank a bit later to ask for a loan, Tightfist shouted no. “How can I loan you money, Ms. Kozysic, when Gonzalez can’t repay what he owes me?”

Dejected, Kozysic phoned up her general contractor, Bill Johnson, and said she couldn’t remodel her storefront. Johnson laid off seven workers. It was a tough thing to tell them right after lunch.

At 2 p.m., Ford announced that it would be offering big rebates on all its new models.

Humbug phoned Ajani immediately, “I have great news. Unless that unexpected tax bill is massive, you are still going to be able to afford the car you wanted!”

“I don’t have an expected tax bill,” Ajani said. “My accountant made an error. It was all a mistake.”

“Excellent!” exclaimed Humbug. “Now you can afford that lovely new car.”

“Not possible,” replied Ajani in a grim tone. “Business has been lousy.”

“I’m sorry to hear that. What’s going on?”

“I haven’t seen Tanaka, Goldman, Gonzalez, Tightfist, or Kozysic for over a month. How can I survive if they don’t patronize my shop?”

SUMMARY

L030.1 Describe how changes in income affect consumption (and saving).

Other things equal, a direct (positive) relationship exists between income and consumption and income and saving. The consumption and saving schedules show the various amounts that households intend to consume and save at the various income and output levels, assuming a fixed price level.

The *average* propensities to consume and save show the fractions of any total income that are consumed and saved; $APC + APS = 1$. The *marginal* propensities to consume and save show the fractions of any change in total income that are consumed and saved; $MPC + MPS = 1$.

L030.2 List and explain factors other than income that can affect consumption.

The locations of the consumption and saving schedules (as they relate to real GDP) are determined by (a) the amount of wealth owned by households, (b) expectations of future prices and incomes, (c) real interest rates, (d) household debt, and (e) tax levels. The consumption and saving schedules are relatively stable.

L030.3 Explain how changes in real interest rates affect investment.

The immediate determinants of investment are (a) the expected rate of return and (b) the real rate of interest. The economy’s investment demand curve is found by cumulating investment projects, arraying them in descending order according to their expected rates of return,

graphing the result, and applying the rule that investment should be undertaken up to the point at which the real interest rate, i , equals the expected rate of return, r . The investment demand curve reveals an inverse (negative) relationship between the interest rate and the level of aggregate investment.

Shifts of the investment demand curve can occur as the result of changes in (a) the acquisition, maintenance, and operating costs of capital goods; (b) business taxes; (c) technology; (d) the stocks of capital goods on hand; and (e) expectations.

Either changes in interest rates or shifts of the investment demand curve can change the level of investment.

L030.4 Identify and explain factors other than the real interest rate that can affect investment.

The durability of capital goods, the irregular occurrence of major innovations, profit volatility, and the variability of expectations all contribute to the instability of investment spending.

L030.5 Illustrate how changes in investment (or one of the other components of total spending) can increase or decrease real GDP by a multiple amount.

Through the multiplier effect, an increase in investment spending (or consumption spending, government purchases, or net export spending) ripples through the economy, ultimately creating a magnified increase in real GDP. The multiplier is the ultimate change in GDP divided by the initiating change in investment or some other component of spending.

The multiplier is equal to the reciprocal of the marginal propensity to save: The greater is the marginal propensity to save, the smaller is the multiplier. Also, the greater is the marginal propensity to consume, the larger is the multiplier.

Economists disagree on the size of the actual multiplier in the United States, with estimates ranging all the way from 2.5 to 0. But all estimates of actual-economy multipliers are less than the multiplier in our purposefully simple text illustrations.

TERMS AND CONCEPTS

45° (degree) line	average propensity to save (APS)	expected rate of return
consumption schedule	marginal propensity to consume (MPC)	investment demand curve
saving schedule	marginal propensity to save (MPS)	multiplier
break-even income	wealth effect	
average propensity to consume (APC)	paradox of thrift

DISCUSSION QUESTIONS

1. Precisely how do the MPC and the APC differ? How does the MPC differ from the MPS? Why must the sum of the MPC and the MPS equal 1? **LO30.1**
2. Why does a downshift of the consumption schedule typically involve an equal upshift of the saving schedule? What is the exception to this relationship? **LO30.2**
3. Why will a reduction in the real interest rate increase investment spending, other things equal? **LO30.3**
4. In what direction will each of the following occurrences shift the investment demand curve, other things equal? **LO30.4**
 - a. An increase in unused production capacity occurs.
 - b. Business taxes decline.
 - c. The costs of acquiring equipment fall.
 - d. Widespread pessimism arises about future business conditions and sales revenues.
 - e. A major new technological breakthrough creates prospects for a wide range of profitable new products.
5. How is it possible for investment spending to increase even in a period in which the real interest rate rises? **LO30.4**
6. Why is investment spending unstable? **LO30.4**
7. Is the relationship between changes in spending and changes in real GDP in the multiplier effect a direct (positive) relationship or is it an inverse (negative) relationship? How does the size of the multiplier relate to the size of the MPC? The MPS? What is the logic of the multiplier-MPC relationship? **LO30.5**
8. Why is the actual multiplier in the U.S. economy less than the multiplier in this chapter's example? **LO30.5**
9. **LAST WORD** What is the central economic idea humorously illustrated in the Last Word "Toppling Dominoes"? How does the central idea relate to economic recessions, on the one hand, and vigorous economic expansions, on the other?

REVIEW QUESTIONS

1. What are the variables (the items measured on the axes) in a graph of the (a) consumption schedule and (b) saving schedule? Are the variables inversely (negatively) related or are they directly (positively) related? What is the fundamental reason that the levels of consumption and saving in the United States are each higher today than they were a decade ago? **LO30.1**
2. In year 1, Adam earns \$1,000 and saves \$100. In year 2, Adam gets a \$500 raise so that he earns a total of \$1,500. Out of that \$1,500, he saves \$200. What is Adam's MPC out of his \$500 raise? **LO30.1**
 - a. 0.50.
 - b. 0.75.
 - c. 0.80.
 - d. 1.00.
3. If the MPS rises, then the MPC will: **LO30.1**
 - a. Fall.
 - b. Rise.
 - c. Stay the same.
4. In what direction will each of the following occurrences shift the consumption and saving schedules, other things equal? **LO30.2**
 - a. A large decrease in real estate values, including private homes.
 - b. A sharp, sustained increase in stock prices.
 - c. A 5-year increase in the minimum age for collecting Social Security benefits.
 - d. An economywide expectation that a recession is over and that a robust expansion will occur.
 - e. A substantial increase in household borrowing to finance auto purchases.

5. Irving owns a chain of movie theaters. He is considering whether he should build a new theater downtown. The expected rate of return is 15 percent per year. He can borrow money at a 12 percent interest rate to finance the project. Should Irving proceed with this project? **LO30.3**
- Yes.
 - No.
6. Which of the following scenarios will shift the investment demand curve right? **LO30.4**
Select **one or more** answers from the choices shown.
- Business taxes increase.
 - The expected return on capital increases.
 - Firms have a lot of unused production capacity.
 - Firms are planning on increasing their inventories.
7. True or False: Real GDP is more volatile (variable) than gross investment. **LO30.4**
8. If a \$50 billion initial increase in spending leads to a \$250 billion change in real GDP, how big is the multiplier? **LO30.5**
- 1.0.
 - 2.5.
 - 4.0.
 - 5.0.
9. True or False: Larger MPCs imply larger multipliers. **LO30.5**

PROBLEMS

1. Refer to the table below. **LO30.1**
- Fill in the missing numbers in the table.
 - What is the break-even level of income in the table? What is the term that economists use for the saving situation shown at the \$240 level of income?
 - For each of the following items, indicate whether the value in the table is either constant or variable as income changes: the MPS, the APC, the MPC, the APS.

Level of Output and Income (GDP = DI)	Consumption	Saving	APC	APS	MPC	MPS

2. Suppose that disposable income, consumption, and saving in some country are \$200 billion, \$150 billion, and \$50 billion, respectively. Next, assume that disposable income increases by \$20 billion, consumption rises by \$18 billion, and saving goes up by \$2 billion. What is the economy's MPC? Its MPS? What was the APC before the increase in disposable income? After the increase? **LO30.1**
3. **ADVANCED ANALYSIS** Suppose that the linear equation for consumption in a hypothetical economy is $C = 40 + 0.8Y$. Also suppose that income (Y) is \$400. Determine (a) the marginal propensity to consume, (b) the marginal propensity to save, (c) the level of consumption, (d) the average propensity to consume, (e) the level of saving, and (f) the average propensity to save. **LO30.1**
4. **ADVANCED ANALYSIS** Linear equations for the consumption and saving schedules take the general form $C = a + bY$ and $S = -a + (1 - b)Y$, where C , S , and Y are consumption, saving,

and national income, respectively. The constant a represents the vertical intercept, and b represents the slope of the consumption schedule. **LO30.1, LO30.2**

- a. Use the following data to substitute numerical values for a and b in the consumption and saving equations.

National Income (Y)	Consumption (C)
\$ 0	\$ 80
100	140
200	200
300	260
400	320

- b. What is the economic meaning of b ? Of $(1 - b)$?
- c. Suppose that the amount of saving that occurs at each level of national income falls by \$20 but that the values of

- b and $(1 - b)$ remain unchanged. Restate the saving and consumption equations inserting the new numerical values, and cite a factor that might have caused the change.
- Use your completed table for problem 1 to solve this problem. Suppose the wealth effect is such that \$10 changes in wealth produce \$1 changes in consumption at each level of income. If real estate prices tumble such that wealth declines by \$80, what will be the new level of consumption and saving at the \$340 billion level of disposable income? The new level of saving? **L030.2**
 - Suppose a handbill publisher can buy a new duplicating machine for \$500 and the duplicator has a 1-year life. The machine is expected to contribute \$550 to the year's net revenue. What is the expected rate of return? If the real interest rate at which funds can be borrowed to purchase the machine is 8 percent, will the publisher choose to invest in the machine? Will it invest in the machine if the real interest rate is 9 percent? If it is 11 percent? **L030.3**
 - Assume there are no investment projects in the economy that yield an expected rate of return of 25 percent or more. But suppose there are \$10 billion of investment projects yielding expected returns of between 20 and 25 percent; another \$10 billion yielding between 15 and 20 percent; another \$10 billion between 10 and 15 percent; and so forth. Cumulate these data and present them graphically, putting the expected rate of return (and the real interest rate) on the vertical axis and the amount of investment on the horizontal axis. What will be the equilibrium level of aggregate investment if the real interest rate is (a) 15 percent, (b) 10 percent, and (c) 5 percent? **L030.3**
 - Refer to the table in Figure 30.5 and suppose that the real interest rate is 6 percent. Next, assume that some factor changes such that the expected rate of return declines by 2 percentage points at each prospective level of investment. Assuming no change in the real interest rate, by how much and in what direction will investment change? Which of the following might cause this change: (a) a decision to increase inventories; (b) an increase in excess production capacity? **L030.4**
 - What will the multiplier be when the MPS is 0, 0.4, 0.6, and 1? What will it be when the MPC is 1, 0.90, 0.67, 0.50, and 0? How much of a change in GDP will result if firms increase their level of investment by \$8 billion and the MPC is 0.80? If the MPC instead is 0.67? **L030.5**
 - Suppose that an initial \$10 billion increase in investment spending expands GDP by \$10 billion in the first round of the multiplier process. If GDP and consumption both rise by \$6 billion in the second round of the process, what is the MPC in this economy? What is the size of the multiplier? If, instead, GDP and consumption both rose by \$8 billion in the second round, what would have been the size of the multiplier? **L030.5**

The Aggregate Expenditures Model

Learning Objectives

- L031.1** Explain how sticky prices relate to the aggregate expenditures model.
- L031.2** Explain how an economy's investment schedule is derived from the investment demand curve and an interest rate.
- L031.3** Illustrate how economists combine consumption and investment to depict an aggregate expenditures schedule for a private closed economy and how that schedule can be used to demonstrate the economy's equilibrium level of output (where the total quantity of goods produced equals the total quantity of goods purchased).
- L031.4** Discuss the two other ways to characterize the equilibrium level of real GDP in a private closed economy: $\text{saving} = \text{investment}$ and no unplanned changes in inventories.
- L031.5** Analyze how changes in equilibrium real GDP can occur in the aggregate expenditures model and describe how those changes relate to the multiplier.
- L031.6** Explain how economists integrate the international sector (exports and imports) into the aggregate expenditures model.
- L031.7** Explain how economists integrate the public sector (government expenditures and taxes) into the aggregate expenditures model.
- L031.8** Differentiate between equilibrium GDP and full-employment GDP and identify and describe the nature and causes of "recessionary expenditure gaps" and "inflationary expenditure gaps."

In previous chapters we answered in detail two of the most critical questions in macroeconomics: How is an economy's output measured? Why does an economy grow? But we have been relatively general in addressing two other important questions: What determines the level of GDP, given a nation's production capacity? What causes real GDP to rise in one period and to fall in another? To provide more thorough answers to these two questions, we construct the aggregate expenditures model, which has its origins in 1936 in the writings of British economist John Maynard Keynes (pronounced "Caines"). The basic premise of the

aggregate expenditures model—also known as the “Keynesian cross” model—is that the amount of goods and services produced and therefore the level of employment depend directly on the level of aggregate expenditures

(total spending). Businesses will produce only a level of output that they think they can profitably sell. They will idle their workers and machinery when there are no markets for their goods and services.

Assumptions and Simplifications

L031.1 Explain how sticky prices relate to the aggregate expenditures model.

The simplifying assumptions underpinning the aggregate expenditures model reflect the economic conditions that were prevalent during the Great Depression. As discussed in this chapter’s Last Word, Keynes created the model during the middle of the Great Depression in the hopes of understanding both why the Great Depression had happened as well as how it might be ended.

The most fundamental assumption behind the aggregate expenditures model is that prices in the economy are fixed. In the terminology of Chapter 26, the aggregate expenditures model is an extreme version of a sticky price model. In fact, it is a stuck-price model because the price level cannot change at all.

Keynes made this simplifying assumption because he had observed that prices had not declined sufficiently during the Great Depression to boost spending and maintain output and employment at their pre-Depression levels. Such price declines had been predicted by macroeconomic theories that were popular before the Great Depression. But actual prices did not fall sufficiently during the Great Depression, and the economy sank far below its potential output. Real GDP in the United States declined by 27 percent from 1929 to 1933, and the unemployment rate rose to 25 percent. Thousands of factories sat idle, gathering dust and producing nothing, because nobody wanted to buy their output.

To Keynes, this massive unemployment of labor and capital resulted from firms reacting to information about how much they should produce. As households and businesses greatly reduced their spending, inventories of unsold goods rocketed. Unable or unwilling to slash their prices, firms could not sell all the goods they had already produced. So they greatly reduced their current production. This meant discharging workers, idling production lines, and even closing entire factories. Keynes thought that a new economic model was needed to show how all this could have happened and how it might be reversed.

The Keynesian aggregate expenditures model is not just of historical interest. It is still insightful even today because many prices in the modern economy are inflexible downward over relatively short periods of time. The aggregate expenditures model therefore can help us understand how the modern economy is likely to initially adjust to various economic

shocks over shorter periods of time. For example, it clarifies aspects of the severe 2007–2009 recession, such as why unexpected initial declines in spending caused even larger declines in real GDP. It also illuminates the thinking underlying the stimulus programs (tax cuts, government spending increases) enacted by the government during the recession.

We will build up the aggregate expenditures model in simple stages. Let’s first look at aggregate expenditures and equilibrium GDP in a *private closed economy*—one without international trade or government. Then we will “open” the “closed” economy to exports and imports and also convert our “private” economy to a more realistic “mixed” economy that includes government purchases (or, more loosely, “government spending”) and taxes.

In addition, until we introduce taxes into the model, we will assume that real GDP equals disposable income (DI). For instance, if \$500 billion of output is produced as GDP, households will receive exactly \$500 billion of disposable income that they can then consume or save. And finally, unless specified otherwise, we will assume (as Keynes did) that the presence of excess production capacity and unemployed labor implies that an increase in aggregate expenditures will increase real output and employment without raising the price level.

Consumption and Investment Schedules

L031.2 Explain how an economy’s investment schedule is derived from the investment demand curve and an interest rate. In the private closed economy, the two components of aggregate expenditures are consumption, C , and gross investment, I_g . Because we examined the *consumption schedule* (Figure 30.2a) in the previous chapter, there is no need to repeat that analysis here. But to add the investment decisions of businesses to the consumption plans of households, we need to construct an investment schedule showing the amounts business firms collectively intend to invest—their **planned investment**—at each possible level of GDP. Such a schedule represents the investment plans of businesses in the same way the consumption schedule represents the consumption plans of households. In developing the investment schedule, we will assume that this planned investment is independent of the level of current disposable income or real output.

FIGURE 31.1 (a) The investment demand curve and (b) the investment schedule. (a) The level of investment spending (here, \$20 billion) is determined by the real interest rate (here, 8 percent) together with the investment demand curve ID . (b) The investment schedule I_g relates the amount of investment (\$20 billion) determined in (a) to the various levels of GDP.

Suppose the investment demand curve is as shown in Figure 31.1a and the current real interest rate is 8 percent. This means that firms will spend \$20 billion on investment goods. Our assumption tells us that this \$20 billion of investment will occur at both low and high levels of GDP. The line I_g in Figure 31.1b shows this graphically; it is the economy's **investment schedule**. You should not confuse this investment schedule I_g with the investment demand curve ID in Figure 31.1a. The investment schedule shows the amount of investment forthcoming at each level of GDP. As indicated in Figure 31.1b, the interest rate and investment demand curve together determine this amount (\$20 billion). Table 31.1 shows the investment schedule in tabular form. Note that investment (I_g) in column 2 is \$20 billion at all levels of real GDP.

Equilibrium GDP: $C + I_g = \text{GDP}$

L031.3 Illustrate how economists combine consumption and investment to depict an aggregate expenditures schedule for a private closed economy and how that schedule can be used to demonstrate the economy's equilibrium level of output (where the total quantity of goods produced equals the total quantity of goods purchased).

Now let's combine the consumption schedule of Chapter 30 and the investment schedule here to explain the equilibrium levels of output, income, and employment in the private closed economy.

Tabular Analysis

Columns 2 through 5 in Table 31.2 repeat the consumption and saving schedules of Table 30.1 and the investment schedule of Table 31.1.

Real Domestic Output Column 2 in Table 31.2 lists the various possible levels of total output—of real GDP—that the private sector might produce. Firms would be willing to produce any one of these 10 levels of output just as long as the revenue that they receive from selling any particular level equals or exceeds the costs they would incur to produce it. Those costs are the factor payments needed to obtain the required amounts of land, labor, capital, and entrepreneurship. For example, firms would be willing to produce \$370 billion of output if the costs of production (wages, rents, interest, and the normal profit needed to attract entrepreneurship) are less than or equal to the \$370 billion in revenue that they would get from selling the output.

*If depreciation and net foreign factor income are zero, government is ignored, and it is assumed that all saving occurs in the household sector of the economy, then GDP as a measure of domestic output is equal to NI, PI, and DI. This means that households receive a DI equal to the value of total output.

Aggregate Expenditures In the private closed economy of Table 31.2, aggregate expenditures consist of consumption (column 3) plus investment (column 5). Their sum is shown in column 6, which along with column 2 makes up the **aggregate expenditures schedule** for the private closed economy. This schedule shows the amount ($C + I_g$) that will be spent at each possible output or income level.

At this point we are working with *planned investment*—the data in column 5, Table 31.2. These data show the amounts firms plan or intend to invest, not the amounts they actually will invest if there are unplanned changes in inventories. More about that shortly.

Equilibrium GDP Of the 10 possible levels of GDP in Table 31.2, which is the equilibrium level? Which total output is the economy capable of sustaining?

The equilibrium output is that output whose production creates total spending just sufficient to purchase that output. So the equilibrium level of GDP is the level at which the total quantity of goods produced (GDP) equals the total quantity of goods purchased ($C + I_g$). In the private closed economy, the **equilibrium GDP** is where

$$C + I_g = \text{GDP}$$

If you look at the domestic output levels in column 2 and the aggregate expenditures levels in column 6, you will see that this equality exists only at \$470 billion of GDP (row 6). That is the only output at which economywide spending is precisely equal to the amount needed to move that output off the shelves. At \$470 billion of GDP, the annual rates of production and spending are in balance. There is no overproduction, which would result in a piling up of unsold goods and consequently

cutbacks in the production rate. Nor is there an excess of total spending, which would draw down inventories of goods and prompt increases in the rate of production. In short, there is no reason for businesses to alter this rate of production; \$470 billion is the equilibrium GDP.

Disequilibrium No level of GDP other than the equilibrium level of GDP can be sustained. At levels of GDP *less than* equilibrium, spending always exceeds GDP. If, for example, firms produced \$410 billion of GDP (row 3 in Table 31.2), they would find it would yield \$405 billion in consumer spending. Supplemented by \$20 billion of planned investment, aggregate expenditures ($C + I_g$) would be \$425 billion, as shown in column 6. The economy would provide an annual rate of spending more than sufficient to purchase the \$410 billion of annual production. Because buyers would be taking goods off the shelves faster than firms could produce them, an unplanned decline in business inventories of \$15 billion would occur (column 7) if this situation continued. But businesses can adjust to such an imbalance between aggregate expenditures and real output by stepping up production. Greater output will increase employment and total income. This process will continue until the equilibrium level of GDP is reached (\$470 billion).

The reverse is true at all levels of GDP *greater than* the \$470 billion equilibrium level. Businesses will find that these total outputs fail to generate the spending needed to clear the shelves of goods. Being unable to recover their costs, businesses will cut back on production. To illustrate: At the \$510 billion output (row 8), business managers would find spending is insufficient to permit the sale of all that output. Of the \$510 billion of income that this output creates, \$480 billion would be received back by businesses as consumption

FIGURE 31.2 Equilibrium GDP in a private closed economy. The aggregate expenditures schedule, $C + I_g$, is determined by adding the investment schedule I_g to the upsloping consumption schedule C . Since investment is assumed to be the same at each level of GDP, the vertical distances between C and $C + I_g$ do not change. Equilibrium GDP is determined where the aggregate expenditures schedule intersects the 45° line, in this case at \$470 billion.

QUICK QUIZ FOR FIGURE 31.2

- In this figure, the slope of the aggregate expenditures schedule $C + I_g$:
 - increases as real GDP increases.
 - falls as real GDP increases.
 - is constant and equals the MPC.
 - is constant and equals the MPS.
- At all points on the 45° line:
 - equilibrium GDP is possible.
 - aggregate expenditures exceed real GDP.
 - consumption exceeds investment.
 - aggregate expenditures are less than real GDP.
- The \$490 billion level of real GDP is not at equilibrium because:
 - investment exceeds consumption.
 - consumption exceeds investment.
 - planned $C + I_g$ exceeds real GDP.
 - planned $C + I_g$ is less than real GDP.
- The \$430 billion level of real GDP is not at equilibrium because:
 - investment exceeds consumption.
 - consumption exceeds investment.
 - planned $C + I_g$ exceeds real GDP.
 - planned $C + I_g$ is less than real GDP.

spending. Though supplemented by \$20 billion of planned investment spending, total expenditures (\$500 billion) would still be \$10 billion below the \$510 billion quantity produced. If this imbalance persisted, \$10 billion of inventories would pile up (column 7). But businesses can adjust to this unintended accumulation of unsold goods by cutting back on the rate of production. The resulting decline in output would mean fewer jobs and a decline in total income.

Graphical Analysis

We can demonstrate the same analysis graphically. In **Figure 31.2 (Key Graph)** the 45° line developed in Chapter 30

now takes on increased significance. Recall that at any point on this line, the value of what is being measured on the horizontal axis (here, GDP) is equal to the value of what is being measured on the vertical axis (here, aggregate expenditures, or $C + I_g$). Having discovered in our tabular analysis that the equilibrium level of domestic output is determined where $C + I_g$ equals GDP, we can say that the 45° line in Figure 31.2 is a graphical statement of that equilibrium condition.

Now we must graph the aggregate expenditures schedule onto Figure 31.2. To do this, we duplicate the consumption schedule C in Figure 30.2a and add to it vertically the constant \$20 billion amount of investment I_g from Figure 31.1b. This \$20 billion is the amount we assumed firms plan to

invest at all levels of GDP. Or, more directly, we can plot the $C + I_g$ data in column 6, Table 31.2.

Observe in Figure 31.2 that the aggregate expenditures line $C + I_g$ shows that total spending rises with income and output (GDP), but not as much as income rises. That is true because the marginal propensity to consume—the slope of line C —is less than 1. A part of any increase in income will be saved rather than spent. And because the aggregate expenditures line $C + I_g$ is parallel to the consumption line C , the slope of the aggregate expenditures line also equals the MPC for the economy and is less than 1. For our particular data, aggregate expenditures rise by \$15 billion for every \$20 billion increase in real output and income because \$5 billion of each \$20 billion increment is saved. Therefore, the slope of the aggregate expenditures line is 0.75 ($= \Delta\$15/\Delta\20).

The equilibrium level of GDP is determined by the intersection of the aggregate expenditures schedule and the 45° line. This intersection locates the only point at which aggregate expenditures (on the vertical axis) are equal to GDP (on the horizontal axis). Because Figure 31.2 is based on the data in Table 31.2, we once again find that equilibrium output is \$470 billion. Observe that consumption at this output is \$450 billion and investment is \$20 billion.

It is evident from Figure 31.2 that no levels of GDP *above* the equilibrium level are sustainable because at those levels $C + I_g$ falls short of GDP. Graphically, the aggregate expenditures schedule lies below the 45° line in those situations. At the \$510 billion GDP level, for example, $C + I_g$ is only \$500 billion. This underspending causes inventories to rise, prompting firms to readjust production downward, in the direction of the \$470 billion output level.

Conversely, at levels of GDP *below* \$470 billion, the economy wants to spend in excess of what businesses are producing. Then $C + I_g$ exceeds total output. Graphically, the aggregate expenditures schedule lies above the 45° line. At the \$410 billion GDP level, for example, $C + I_g$ totals \$425 billion. This excess spending causes inventories to fall below their planned level, prompting firms to adjust production upward, in the direction of the \$470 billion output level. Once production reaches that level, it will be sustained there indefinitely unless there is some change in the location of the aggregate expenditures line.

Other Features of Equilibrium GDP

LO31.4 Discuss the two other ways to characterize the equilibrium level of real GDP in a private closed economy: saving = investment and no unplanned changes in inventories. We have seen that $C + I_g = \text{GDP}$ at equilibrium in the private closed economy. A closer look at Table 31.2 reveals two more characteristics of equilibrium GDP:

- Saving and *planned* investment are equal ($S = I_g$).
- There are no *unplanned* changes in inventories.

Saving Equals Planned Investment

As shown by row 6 in Table 31.2, saving and planned investment are both \$20 billion at the \$470 billion equilibrium level of GDP.

Saving is a **leakage** or withdrawal of spending from the economy's circular flow of income and expenditures. Saving is what causes consumption to be less than total output or GDP. Because of saving, consumption by itself is insufficient to remove domestic output from the shelves, apparently setting the stage for a decline in total output.

However, firms do not intend to sell their entire output to consumers. Some of that output will be capital goods sold to other businesses. Investment—the purchases of capital goods—is therefore an **injection** of spending into the income-expenditures stream. As an adjunct to consumption, investment is thus a potential replacement for the leakage of saving.

If the leakage of saving at a certain level of GDP exceeds the injection of investment, then $C + I_g$ will be less than GDP and that level of GDP cannot be sustained. Any GDP for which saving exceeds investment is an above-equilibrium GDP. Consider GDP of \$510 billion (row 8 in Table 31.2). Households will save \$30 billion, but firms will plan to invest only \$20 billion. This \$10 billion excess of saving over planned investment will reduce total spending to \$10 billion below the value of total output. Specifically, aggregate expenditures will be \$500 billion while real GDP is \$510 billion. This spending deficiency will reduce real GDP.

Conversely, if the injection of investment exceeds the leakage of saving, then $C + I_g$ will be greater than GDP and drive GDP upward. Any GDP for which investment exceeds saving is a below-equilibrium GDP. For example, at a GDP of \$410 billion (row 3 in Table 31.2), households will save only \$5 billion, but firms will invest \$20 billion. So investment exceeds saving by \$15 billion. The small leakage of saving at this relatively low GDP level is more than compensated for by the larger injection of investment spending. That causes $C + I_g$ to exceed GDP and drives GDP higher.

Only where $S = I_g$ —where the leakage of saving of \$20 billion is exactly offset by the injection of planned investment of \$20 billion—will aggregate expenditures ($C + I_g$) equal real output (GDP). That $C + I_g = \text{GDP}$ equality is what defines the equilibrium GDP.

No Unplanned Changes in Inventories

As part of their investment plans, firms may decide to increase or decrease their inventories. But, as confirmed in line 6 of Table 31.2, there are no **unplanned changes in inventories** at equilibrium GDP. This fact, along with $C + I_g = \text{GDP}$, and $S = I_g$ is a characteristic of equilibrium GDP in the private closed economy.

Unplanned changes in inventories play a major role in achieving equilibrium GDP. Consider, as an example, the \$490 billion *above-equilibrium* GDP shown in row 7 of Table 31.2. What happens if firms produce that output, thinking they can sell it? Households save \$25 billion of their \$490 billion DI, so

consumption is only \$465 billion. Planned investment—which includes *planned* changes in inventories—is \$20 billion (column 5). So aggregate expenditures ($C + I_g$) are \$485 billion and sales fall short of production by \$5 billion. Firms retain that extra \$5 billion of goods as an *unplanned* increase in inventories (column 7). It results from the failure of total spending to remove total output from the shelves.

Because changes in inventories are a part of investment, we note that *actual investment* is \$25 billion. It consists of \$20 billion of planned investment *plus* the \$5 billion unplanned increase in inventories. Actual investment equals the saving of \$25 billion, even though saving exceeds planned investment by \$5 billion. Because firms cannot earn profits by accumulating unwanted inventories, the \$5 billion unplanned increase in inventories will prompt them to cut back employment and production. GDP will fall to its equilibrium level of \$470 billion, at which unplanned changes in inventories are zero.

Now look at the *below-equilibrium* \$450 billion output (row 5, Table 31.2). Because households save only \$15 billion of their \$450 billion DI, consumption is \$435 billion. Planned investment by firms is \$20 billion, so aggregate expenditures are \$455 billion. Sales exceed production by \$5 billion. This is so only because a \$5 billion unplanned decrease in business inventories has occurred. Firms must *disinvest* \$5 billion in inventories (column 7). Note again that actual investment is \$15 billion (\$20 billion planned *minus* the \$5 billion decline in inventory investment) and is equal to saving of \$15 billion, even though planned investment exceeds saving by \$5 billion. The unplanned decline in inventories, resulting from the excess of sales over production, will encourage firms to expand production. GDP will rise to \$470 billion, at which unplanned changes in inventories are zero.

When economists say differences between investment and saving can occur and bring about changes in equilibrium GDP, they are referring to planned investment and saving. Equilibrium occurs only when planned investment and saving are equal. But when unplanned changes in inventories are considered, investment and saving are always equal, regardless of the level of GDP. That is true because actual investment consists of planned investment and unplanned investment (unplanned changes in inventories). Unplanned changes in inventories act as a balancing item that equates the actual amounts saved and invested in any period.

Changes in Equilibrium GDP and the Multiplier

LO31.5 Analyze how changes in equilibrium real GDP can occur in the aggregate expenditures model and describe how those changes relate to the multiplier.

In the previous chapter, we established that an initial change in spending can cause a greater change in real output through the multiplier effect. In equation form,

$$\text{Multiplier} = \frac{\text{change in real GDP}}{\text{initial change in spending}}$$

Further, we discovered that the size of the multiplier depends on the size of the MPS in the economy:

$$\text{Multiplier} = \frac{1}{\text{MPS}}$$

(Because the multiplier is such an important element of the aggregate expenditures model, we highly recommend that you quickly review Figure 30.8 at this time.)

In a private closed economy, the equilibrium GDP will change in response to changes in either the investment schedule or the consumption schedule. Because changes in the investment schedule are the main sources of instability, we will direct our attention toward them.

Figure 31.3 shows the effect of changes in investment spending on the equilibrium real GDP. Suppose that the expected rate of return on investment rises or that the real interest rate falls such that investment spending increases by \$5 billion. That would be shown as an upward shift of the investment schedule in Figure 31.1b. In Figure 31.3, the \$5 billion increase of investment spending will increase aggregate expenditures from $(C + I_g)_0$ to $(C + I_g)_1$ and raise equilibrium real GDP from \$470 billion to \$490 billion.

If the expected rate of return on investment decreases or if the real interest rate rises, investment spending will decline by, say, \$5 billion. That would be shown as a downward shift of the investment schedule in Figure 31.1b and a downward shift of the aggregate expenditures schedule from $(C + I_g)_0$ to $(C + I_g)_2$ in Figure 31.3. Equilibrium GDP will fall from \$470 billion to \$450 billion.

In our examples, a \$5 billion change in investment spending leads to a \$20 billion change in output and income. So the *multiplier* is 4 ($= \$20/\5). The MPS is 0.25, meaning that for every \$1 billion of new income, \$0.25 billion of new saving occurs. Therefore, \$20 billion of new income is needed to generate \$5 billion of new saving. Once that increase in income and saving occurs, the economy is back in equilibrium— $C + I_g = \text{GDP}$; saving and investment are equal; and there are no unplanned changes in inventories. You can see, then, why the multiplier is equal to $1/\text{MPS}$ and that the multiplier process is an integral part of the aggregate expenditures model.

QUICK REVIEW 31.1

- ✓ In a private closed economy, equilibrium GDP occurs where aggregate expenditures equal real domestic output ($C + I_g = \text{GDP}$).
- ✓ At equilibrium GDP, saving equals planned investment ($S = I_g$) and unplanned changes in inventories are zero.
- ✓ Actual investment consists of planned investment plus unplanned changes in inventories (+ or −) and is always equal to saving in a private closed economy.
- ✓ Through the multiplier effect, an initial change in investment spending can cause a magnified change in domestic output and income.

FIGURE 31.3 Changes in the aggregate expenditures schedule and the multiplier effect. An upward shift of the aggregate expenditures schedule from $(C + I_g)_0$ to $(C + I_g)_1$ will increase the equilibrium GDP. Conversely, a downward shift from $(C + I_g)_0$ to $(C + I_g)_2$ will lower the equilibrium GDP. The extent of the changes in equilibrium GDP will depend on the size of the multiplier, which in this case is 4 ($= 20/5$). The multiplier is equal to $1/\text{MPS}$ (here, $4 = 1/.25$).

Adding International Trade

LO31.6 Explain how economists integrate the international sector (exports and imports) into the aggregate expenditures model.

We next move from a private closed economy to a private open economy that incorporates exports (X) and imports (M). Our focus will be on **net exports** (exports minus imports), which may be either positive or negative.

Net Exports and Aggregate Expenditures

Like consumption and investment, exports create domestic production, income, and employment for a nation. Although U.S. goods and services produced for export are sent abroad, foreign spending on those goods and services increases production and creates jobs and incomes in the United States. We must therefore include exports as a component of U.S. aggregate expenditures.

Conversely, when an economy is open to international trade, it will spend part of its income on imports—goods and services produced abroad. To avoid overstating the value of domestic production, we must subtract the amount spent on imported goods because such spending generates production and income abroad rather than at home. So, to correctly measure aggregate expenditures for domestic goods and services, we must subtract expenditures on imports from total spending.

In short, for a private closed economy, aggregate expenditures are $C + I_g$. But for an open economy, aggregate expenditures are $C + I_g + (X - M)$. Or, recalling that net exports

(X_n) equal $(X - M)$, we can say that aggregate expenditures for a private open economy are $C + I_g + X_n$.

The Net Export Schedule

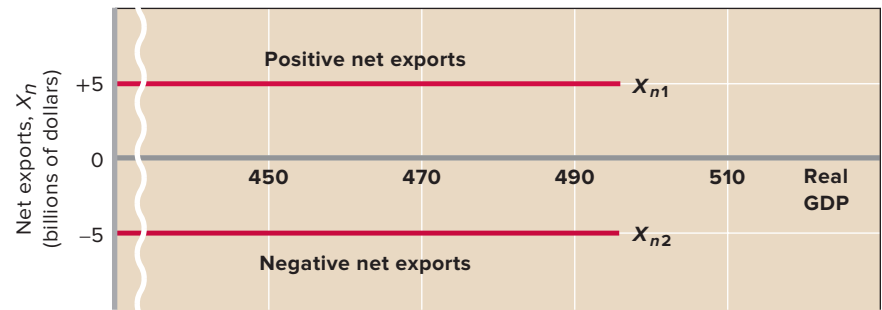

A net export schedule lists the amount of net exports that will occur at each level of GDP. Table 31.3 shows two possible net export schedules for the hypothetical economy represented in Table 31.2. In net export schedule X_{n1} (columns 1 and 2), exports exceed imports by \$5 billion at each level of GDP. Perhaps exports are \$15 billion while imports are \$10 billion. In schedule X_{n2} (columns 1 and 3), imports are \$5 billion higher than exports. Perhaps imports are \$20 billion while exports

(b) Positive net exports elevate the aggregate expenditure schedule from the closed-economy level of $C + I_g$ to the open-economy level of $C + I_g + X_{n1}$. Negative net exports lower the aggregate expenditures schedule from the closed-economy level of $C + I_g$ to the open-economy level of $C + I_g + X_{n2}$.

are \$15 billion. To simplify our discussion, we assume in both schedules that net exports are independent of GDP.¹

Figure 31.4a represents the two net export schedules in Table 31.3. Schedule X_{n1} is above the horizontal axis and depicts positive net exports of \$5 billion at all levels of GDP. Schedule X_{n2} , which is below the horizontal axis, shows negative net exports of \$5 billion at all levels of GDP.

¹In reality, although our exports depend on foreign incomes and are thus independent of U.S. GDP, our imports do vary directly with our own domestic national income. Just as our domestic consumption varies directly with our GDP, so do our purchases of foreign goods. As our GDP rises, U.S. households buy not only more Cadillacs and Harleys, but also more Mercedes and Kawasakis. However, for now we will ignore the complications of the positive relationship between imports and U.S. GDP.

Net Exports and Equilibrium GDP

The aggregate expenditures schedule labeled $C + I_g$ in Figure 31.4b reflects the private closed economy. It shows the combined consumption and gross investment expenditures occurring at each level of GDP. With no foreign sector, the equilibrium GDP is \$470 billion.

But in the private open economy, net exports can be either positive or negative. Let's see how each of the net export schedules in Figure 31.4a affects equilibrium GDP.

Positive Net Exports Suppose the net export schedule is X_{n1} . The \$5 billion of additional net export expenditures by the rest of the world is accounted for by adding that \$5 billion to the $C + I_g$ schedule in Figure 31.4b. Aggregate expenditures at

each level of GDP are then \$5 billion higher than $C + I_g$ alone. The aggregate expenditures schedule for the open economy thus becomes $C + I_g + X_{n1}$. In this case, international trade increases equilibrium GDP from \$470 billion in the private closed economy to \$490 billion in the private open economy. Adding net exports of \$5 billion has increased GDP by \$20 billion, in this case implying a multiplier of 4.

Generalization: Other things equal, positive net exports increase aggregate expenditures and GDP beyond what they would be in a closed economy. Be careful to notice that this increase is the result of exports being larger than imports. This is true because exports and imports have opposite effects on the measurement of domestically produced output. Exports increase real GDP by increasing expenditures on domestically produced output. Imports, by contrast, must be subtracted when calculating real GDP because they are expenditures directed toward output produced abroad. It is only because net exports are positive in this example—so that the expansionary effect of exports outweighs the reductions caused by imports—that we get the overall increase in real GDP. As the next section shows, if net exports are negative, then the reductions caused by imports will outweigh the expansionary effect of exports so that domestic real GDP will decrease.

Negative Net Exports Suppose that net exports are a negative \$5 billion as shown by X_{n2} in Figure 31.4a. This means that our hypothetical economy is importing \$5 billion more of goods than it is exporting. The aggregate expenditures schedule shown as $C + I_g$ in Figure 31.4b therefore overstates the expenditures on domestic output at each level of GDP. We must reduce the sum of expenditures by the \$5 billion net amount spent on imported goods. We do that by subtracting the \$5 billion of net imports from $C + I_g$.

The relevant aggregate expenditures schedule in Figure 31.4b becomes $C + I_g + X_{n2}$ and equilibrium GDP falls from \$470 billion to \$450 billion. Again, a change in net exports of \$5 billion has produced a fourfold change in GDP, reminding us that the multiplier in this example is 4.

This gives us a corollary to our first generalization: Other things equal, negative net exports reduce aggregate expenditures and GDP below what they would be in a closed economy. When imports exceed exports, the contractionary effect of the larger amount of imports outweighs the expansionary effect of the smaller amount of exports, and equilibrium real GDP decreases.

Our generalizations of the effects of net exports on GDP mean that a decline in X_n —a decrease in exports or an increase in imports—reduces aggregate expenditures and contracts a nation's GDP. Conversely, an increase in X_n —the result of either an increase in exports or a decrease in imports—increases aggregate expenditures and expands GDP.

As is shown in Global Perspective 31.1, net exports vary greatly among the major industrial nations.

International Economic Linkages

Our analysis of net exports and real GDP suggests how circumstances or policies abroad can affect U.S. GDP.

Prosperity Abroad A rising level of real output and income among U.S. foreign trading partners enables the United States to sell more goods abroad, thus raising U.S. net exports and increasing U.S. real GDP (assuming initially there is excess capacity). There is good reason for Americans to be interested in the prosperity of our trading partners. Their good fortune enables them to buy more of our exports, increasing our income and enabling us in turn to buy more foreign imports. These imported goods are the ultimate benefit of international trade. Prosperity abroad transfers some of that prosperity to Americans.

Exchange Rates Depreciation of the dollar relative to other currencies enables people abroad to obtain more dollars with each unit of their own currencies. The price of U.S. goods in terms of those currencies will fall, stimulating purchases of U.S. exports. Also, U.S. customers will find they need more dollars to buy foreign goods and, consequently, will reduce their spending on imports. If the economy has available capacity, the increased exports and decreased imports will increase U.S. net exports and expand the nation's GDP.

This last example has been cast only in terms of depreciation of the dollar. You should think through the impact that appreciation of the dollar would have on net exports and equilibrium GDP.

A Caution on Tariffs and Devaluations Because higher net exports increase real GDP, countries often look for ways

to reduce imports and increase exports during recessions or depressions. Thus, a recession might tempt the U.S. federal government to increase tariffs and devalue the international value of the dollar (say, by supplying massive amounts of dollars in the foreign exchange market) to try to increase net exports. Such an increase of net exports would expand domestic production, reduce domestic unemployment, and help the economy recover.

But this interventionist thinking is too simplistic. Suppose that the United States imposes high tariffs on foreign goods to reduce our imports and thus increase our domestic production and employment. Our imports, however, are our trading partners' exports. So when we restrict our imports to stimulate our economy, we depress the economies of our trading partners. They are likely to retaliate against us by imposing tariffs on our products. If so, our exports to them will decline and our net exports may in fact fall. With retaliation in the picture, it is possible that tariffs may decrease, not increase, our net exports.

That unfortunate possibility became a sad reality during the Great Depression of the 1930s, when various nations, including the United States, imposed trade barriers as a way of reducing domestic unemployment. The result was many rounds of retaliation that simply throttled world trade, worsened the depression, and increased unemployment. Abetting the problem were attempts by some nations to increase their net exports by devaluing their currencies. Other nations simply retaliated by devaluing their own currencies. The international exchange rate system collapsed, and world trade spiraled downward. Economic historians agree that tariffs and devaluations during the 1930s were huge policy mistakes!

Nations are tempted to use tariffs and currency devaluations because, *other things equal*, these policies *do* increase net exports and real GDP. But keep in mind that other things aren't likely to stay equal. In particular, other nations will almost certainly retaliate with their own tariffs and devaluations—the final result being lower net exports and lower GDP for those countries and for our own.

QUICK REVIEW 31.2

- ✓ Positive net exports increase aggregate expenditures relative to the closed economy and, other things equal, increase equilibrium GDP.
- ✓ Negative net exports decrease aggregate expenditures relative to the closed economy and, other things equal, reduce equilibrium GDP.
- ✓ In the open economy, changes in (a) prosperity abroad, (b) tariffs, and (c) exchange rates can affect U.S. net exports and therefore U.S. aggregate expenditures and equilibrium GDP.
- ✓ Tariffs and deliberate currency depreciations are unlikely to increase net exports because other nations will retaliate.

Adding the Public Sector

L031.7 Explain how economists integrate the public sector (government expenditures and taxes) into the aggregate expenditures model.

Our final step in constructing the full aggregate expenditures model is to move the analysis from a private (no-government) open economy to an economy with a public sector (sometimes called a “mixed economy”). This means adding government purchases and taxes to the model.

For simplicity, we will assume that government purchases are independent of the level of GDP and do not alter the consumption and investment schedules. Also, government's net tax revenues—total tax revenues less “negative taxes” in the form of transfer payments—are derived entirely from personal taxes. Finally, a fixed amount of taxes is collected regardless of the level of GDP.

Government Purchases and Equilibrium GDP

Suppose the government decides to purchase \$20 billion of goods and services regardless of the level of GDP and tax collections.

Tabular Example Table 31.4 shows the impact of this purchase on the equilibrium GDP. Columns 1 through 4 are carried over from Table 31.2 for the private closed economy, in which the equilibrium GDP was \$470 billion. The only new items are exports and imports in column 5 and government purchases in column 6. (Observe in column 5 that net exports are zero.) As shown in column 7, the addition of government purchases to private spending ($C + I_g + X_n$) yields a new, higher level of aggregate expenditures ($C + I_g + X_n + G$). Comparing columns 1 and 7, we find that aggregate expenditures and real output are equal at a higher level of GDP. Without government purchases, equilibrium GDP was \$470 billion (row 6); *with* government purchases, aggregate expenditures and real output are equal at \$550 billion (row 10). Increases in public spending, like increases in private spending, shift the aggregate expenditures schedule upward and produce a higher equilibrium GDP.

Note, too, that government spending is subject to the multiplier. A \$20 billion increase in government purchases has increased equilibrium GDP by \$80 billion (from \$470 billion to \$550 billion). The multiplier in this example is 4.

This \$20 billion increase in government spending is *not* financed by increased taxes. Shortly, we will demonstrate that increased taxes *reduce* equilibrium GDP.

Graphical Analysis In Figure 31.5, we vertically add \$20 billion of government purchases, G , to the level of private spending, $C + I_g + X_n$. That added \$20 billion raises the aggregate expenditures schedule (private plus public) to $C + I_g + X_n + G$, resulting in an \$80 billion increase in equilibrium GDP, from \$470 to \$550 billion.

**FIGURE 31.5** Government spending and equilibrium GDP. The addition of government expenditures of G to our analysis raises the aggregate expenditures ($C + I_g + X_n + G$) schedule and increases the equilibrium level of GDP, as would an increase in C , I_g , or X_n .

A decline in government purchases G will lower the aggregate expenditures schedule in Figure 31.5 and result in a multiplied decline in the equilibrium GDP. Verify in Table 31.4 that if government purchases were to decline from \$20 billion to \$10 billion, the equilibrium GDP would fall by \$40 billion.

Taxation and Equilibrium GDP

The government not only spends but also collects taxes. Suppose it imposes a **lump-sum tax**, which is a tax of a constant amount or, more precisely, a tax yielding the same amount of tax revenue at each level of GDP. Let's assume this tax is \$20 billion, so that the government obtains \$20 billion of tax

revenue at each level of GDP regardless of the level of government purchases.

Tabular Example In Table 31.5, which continues our example, we find taxes in column 2, and we see in column 3 that disposable (after-tax) income is lower than GDP (column 1) by the \$20 billion amount of the tax. Because households use disposable income both to consume and to save, the tax lowers both consumption and saving. The MPC and MPS tell us how much consumption and saving will decline as a result of the \$20 billion in taxes. Because the MPC is 0.75, the government tax collection of \$20 billion will reduce consumption by \$15 billion ($= 0.75 \times \20 billion). Since the MPS is 0.25, saving will drop by \$5 billion ($= 0.25 \times \20 billion).

Columns 4 and 5 in Table 31.5 list the amounts of consumption and saving at each level of GDP. Note they are \$15 billion and \$5 billion smaller than those in Table 31.4. Taxes reduce disposable income relative to GDP by the amount of the taxes. This decline in DI reduces both consumption and saving at each level of GDP. The extent of the C and S reductions depends on the MPC and the MPS.

To find the effect of taxes on equilibrium GDP, we calculate aggregate expenditures again, as shown in column 9, Table 31.5. Aggregate spending is \$15 billion less at each level of GDP than it was in Table 31.4. The reason is that after-tax consumption, designated by C_a , is \$15 billion less at each level of GDP. A comparison of real output and aggregate expenditures in columns 1 and 9 shows that the aggregate amounts produced and purchased are equal only at \$490 billion of GDP (row 7). The \$20 billion lump-sum tax has reduced equilibrium GDP by \$60 billion, from \$550 billion (row 10, Table 31.4) to \$490 billion (row 7, Table 31.5).

Graphical Analysis In Figure 31.6, the \$20 billion increase in taxes shows up as a \$15 (not \$20) billion decline in the aggregate expenditures ($C_a + I_g + X_n + G$) schedule. This decline in the schedule results solely from a decline in the consumption C component of aggregate expenditures. The equilibrium GDP falls from \$550 billion to \$490 billion because of this tax-caused drop in consumption. With no change in government expenditures, tax increases lower the aggregate expenditures schedule relative to the 45° line and reduce the equilibrium GDP.

In contrast to our previous case, a *decrease* in existing taxes will raise the aggregate expenditures schedule in Figure 31.6 as a result of an increase in consumption at all GDP levels. You should confirm that a tax reduction of \$10 billion (from the present \$20 billion to \$10 billion) would increase the equilibrium GDP from \$490 billion to \$520 billion.

Differential Impacts You may have noted that equal changes in G and T do not have equivalent impacts on GDP. The \$20 billion increase in G in our illustration, subject to the multiplier of 4, produced an \$80 billion increase in real GDP. But the \$20 billion increase in taxes reduced GDP by only \$60 billion. Given an MPC of 0.75, the tax increase of \$20 billion reduced consumption by only \$15 billion (not \$20 billion) because saving also fell by \$5 billion. Subjecting the \$15 billion decline in consumption to the multiplier of 4, we find the tax increase of \$20 billion reduced GDP by \$60 billion (not \$80 billion).

Table 31.5 and Figure 31.6 constitute the complete aggregate expenditures model for an open economy with government. When total spending equals total production, the economy's output is in equilibrium. In the open mixed economy, equilibrium GDP occurs where

$$C_a + I_g + X_n + G = \text{GDP}$$

FIGURE 31.6 Taxes and equilibrium GDP. If the MPC is 0.75, the \$20 billion of taxes will lower the consumption schedule by \$15 billion and cause a \$60 billion decline in the equilibrium GDP. In the open economy with government, equilibrium GDP occurs where C_a (after-tax income) + $I_g + X_n + G = \text{GDP}$. Here that equilibrium is \$490 billion.

Injections, Leakages, and Unplanned Changes in Inventories The related characteristics of equilibrium noted for the private closed economy also apply to the full model. In particular, it is still the case that injections into the income-expenditures stream equal leakages from the income stream. For the private closed economy, $S = I_g$. For the expanded economy, imports and taxes are added leakages. Saving, importing, and paying taxes are all uses of income that subtract from potential consumption. Consumption will now be less than GDP—creating a potential spending gap—in the amount of after-tax saving (S_a), imports (M), and taxes (T). But exports (X) and government purchases (G), along with investment (I_g), are injections into the income-expenditures stream. At the equilibrium GDP, the sum of the leakages equals the sum of injections. In symbols:

$$S_a + M + T = I_g X + G$$

You should use the data in Table 31.5 to confirm this equality between leakages and injections at the equilibrium GDP of \$490 billion. Also, substantiate that a lack of such equality exists at all other possible levels of GDP.

Although not directly shown in Table 31.5, the equilibrium characteristic of “no unplanned changes in inventories” will also be fulfilled at the \$490 billion GDP. Because aggregate expenditures equal GDP, all the goods and services produced will be purchased. There will be no unplanned increase in inventories, so firms will have no incentive to reduce their employment and production. Nor will they experience an unplanned decline in their inventories, which would prompt them to expand their employment and output to replenish their inventories.

Equilibrium versus Full-Employment GDP

LO31.8 Differentiate between equilibrium GDP and full-employment GDP and identify and describe the nature and causes of “recessionary expenditure gaps” and “inflationary expenditure gaps.”

A key point about the equilibrium GDP of the aggregate expenditures model is that it need not equal the economy’s full-employment GDP. In fact, Keynes specifically designed the model so that it could explain situations like the Great Depression, during which the economy was seemingly stuck at a bad equilibrium in which real GDP was far below potential output. As we will show you in a moment, Keynes also used the model to suggest policy recommendations for moving the economy back toward potential output and full employment.

The fact that equilibrium and potential GDP in the aggregate expenditure model need not match also reveals critical insights about the causes of demand-pull inflation. We will first examine the “expenditure gaps” that give rise to differences between equilibrium and potential GDP and then see how the model helps to explain the recession of 2007–2009 and preview the policies used by the federal government to try to halt and reverse it.

Recessionary Expenditure Gap

Suppose in **Figure 31.7 (Key Graph)**, panel (a), that the full-employment level of GDP is \$510 billion and the aggregate expenditures schedule is AE_1 . (For simplicity, we will now dispense with the $C_a + I_g + X_n + G$ labeling.) This schedule intersects the

FIGURE 31.7 **Recessionary and inflationary expenditure gaps.** The equilibrium and full-employment GDPs may not coincide. (a) A recessionary expenditure gap is the amount by which aggregate expenditures at the full-employment GDP fall short of those needed to achieve the full-employment GDP. Here, the \$5 billion recessionary expenditure gap causes a \$20 billion negative GDP gap. (b) An inflationary expenditure gap is the amount by which aggregate expenditures at the full-employment GDP exceed those just sufficient to achieve the full-employment GDP. Here, the inflationary expenditure gap is \$5 billion; this overspending produces demand-pull inflation.

QUICK QUIZ FOR FIGURE 31.7

- In the economy depicted:
 - the MPS is 0.50.
 - the MPC is 0.75.
 - the full-employment level of real GDP is \$530 billion.
 - nominal GDP always equals real GDP.
- The inflationary expenditure gap depicted will cause:
 - demand-pull inflation.
 - cost-push inflation.
 - cyclical unemployment.
 - frictional unemployment.
- The recessionary expenditure gap depicted will cause:
 - demand-pull inflation.
 - cost-push inflation.
 - cyclical unemployment.
 - frictional unemployment.
- In the economy depicted, the \$5 billion inflationary expenditure gap:
 - expands real GDP to \$530 billion.
 - leaves real GDP at \$510 billion but causes inflation.
 - could be remedied by equal \$5 billion increases in taxes and government spending.
 - implies that real GDP exceeds nominal GDP.

45° line to the left of the economy's full-employment output, so the economy's equilibrium GDP of \$490 billion is \$20 billion short of its full-employment output of \$510 billion. According to column 1 in Table 31.2, total employment at the full-employment GDP is 75 million workers. But the economy depicted in Figure 31.7a is employing only 70 million workers; 5 million available workers are not employed. For that reason, the economy is sacrificing \$20 billion of output.

A **recessionary expenditure gap** is the amount by which aggregate expenditures *at the full-employment GDP* fall short of those required to achieve the full-employment GDP. Insufficient total spending contracts or depresses the economy.

Table 31.5 shows that at the full-employment level of \$510 billion (column 1), the corresponding level of aggregate expenditures is only \$505 billion (column 9). The recessionary expenditure gap is thus \$5 billion, the amount by which the aggregate expenditures curve would have to shift upward to realize equilibrium at the full-employment GDP. Graphically, the recessionary expenditure gap is the *vertical* distance (measured at the full-employment GDP) by which the actual aggregate expenditures schedule AE_1 lies below the hypothetical full-employment aggregate expenditures schedule AE_0 . In Figure 31.7a, this recessionary expenditure gap is \$5 billion. Because the multiplier is 4, there is a \$20 billion differential

(the recessionary expenditure gap of \$5 billion times the multiplier of 4) between the equilibrium GDP and the full-employment GDP. This \$20 billion difference is a negative *GDP gap*—an idea we first developed when discussing cyclical unemployment in Chapter 29.

Keynes's Solution to a Recessionary Expenditure Gap

Keynes pointed to two different policies that a government might pursue to close a recessionary expenditure gap and achieve full employment. The first is to increase government spending. The second is to lower taxes. Both work by increasing aggregate expenditures.

Look back at Figure 31.5. There we showed how an increase in government expenditures G will increase overall aggregate expenditures and, consequently, the equilibrium real GDP. Applying this strategy to the situation in Figure 31.7a, government could completely close the \$20 billion negative GDP gap between the initial equilibrium of \$490 billion and the economy's potential output of \$510 billion if it increased spending by the \$5 billion amount of the recessionary expenditure gap. Given the economy's multiplier of 4, the \$5 billion increase in G would create a \$20 billion increase in equilibrium real GDP, thereby bringing the economy to full employment.

Government also could lower taxes to close the recessionary expenditure gap and thus eliminate the negative GDP gap. Look back at Figure 31.6 in which an increase in taxes resulted in lower after-tax consumption spending and a smaller equilibrium real GDP. Keynes simply suggested a reversal of this process: Since an increase in taxes lowers equilibrium real GDP, a decrease in taxes will raise equilibrium real GDP. The decrease in taxes will leave consumers with higher after-tax income. That will lead to higher consumption expenditures and an increase in equilibrium real GDP.

But by how much should the government cut taxes? By exactly \$6.67 billion. That is because the MPC is 0.75. The tax cut of \$6.67 billion will increase consumers' after-tax income by \$6.67 billion. They will then increase consumption spending by 0.75 of that amount, or \$5 billion. This will increase aggregate expenditures by the \$5 billion needed to close the recessionary expenditure gap. The economy's equilibrium real GDP will rise to its potential output of \$510 billion.

But a big warning is needed here: As the economy moves closer to its potential output, it becomes harder to justify Keynes's assumption that prices are stuck. As the economy closes its negative GDP gap, nearly all workers are employed and nearly all factories are operating at or near full capacity. In such a situation, there is no massive oversupply of productive resources to keep prices from rising. In fact, economists know from real-world experience that in such situations prices are not fully stuck. Instead, they become increasingly flexible as the economy moves nearer to potential output.

This fact is one of the major limitations of the aggregate expenditures model and is the reason why we will develop a

different model that can handle inflation in the next chapter. That being said, it is nevertheless true that the aggregate expenditures model is still very useful despite its inability to handle flexible prices. For instance, as we explained in Chapter 26, even an economy operating near full employment will show sticky or even stuck prices in the short run. In such situations, the intuitions of the aggregate expenditures model will still hold true. The benefit of the aggregate demand–aggregate supply model that we develop in the next chapter is that it also can show us what happens over longer periods, as prices (and wages) become more flexible and are increasingly able to adjust.

Inflationary Expenditure Gap

Economists use the term **inflationary expenditure gap** to describe the amount by which an economy's aggregate expenditures *at the full-employment GDP* exceed those just necessary to achieve the full-employment level of GDP. In Figure 31.7b, there is a \$5 billion inflationary expenditure gap at the \$510 billion full-employment GDP. This is shown by the vertical distance between the actual aggregate expenditures schedule AE_2 and the hypothetical schedule AE_0 that would be just sufficient to achieve the \$510 billion full-employment GDP. Thus, the inflationary expenditure gap is the amount by which the aggregate expenditures schedule would have to shift downward to realize equilibrium at the full-employment GDP.

But why does the name “inflationary expenditure gap” contain the word *inflationary*? In particular, what does the situation depicted in Figure 31.7b have to do with inflation? The answer lies in the answer to a different question: *Could the economy actually achieve and maintain an equilibrium real GDP that is substantially above the full-employment output level?*

The unfortunate answer is no. It is unfortunate because if such a thing were possible, then the government could make real GDP as high as it wanted by simply increasing G to an arbitrarily high number. Graphically, it could raise the AE_2 curve in Figure 31.7b as far up as it wanted, thereby increasing equilibrium real GDP as high as it wanted. Living standards would skyrocket! But this is not possible because, by definition, all the available workers in the economy are fully employed at the full-employment output level. Producing slightly more than the full-employment output level for a few months might be possible if you could convince all the workers to work overtime day after day. But there simply is not enough labor to have the economy produce at much more than potential output for any extended period of time.

So what *does* happen in situations in which aggregate expenditures are so high that the model predicts an equilibrium level of GDP beyond potential output? The answer is twofold. First, the economy ends up producing either at potential output or just above potential output due to the limited supply of labor. Second, the economy experiences demand-pull inflation. With the supply of output limited by the supply of labor, high levels of aggregate expenditures simply drive up prices.

Say's Law, the Great Depression, and Keynes

The Aggregate Expenditure Theory Emerged as a Critique of Classical Economics and as a Response to the Great Depression.

Until the Great Depression of the 1930s, many prominent economists, including David Ricardo (1772–1823) and John Stuart Mill (1806–1873), believed that the market system would ensure full employment of an economy's resources. These so-called *classical economists* acknowledged that now and then abnormal circumstances such as wars, political upheavals, droughts, speculative crises, and gold rushes would occur, deflecting the economy from full-employment status. But when such deviations occurred, the economy would automatically adjust and soon return to full-employment output. For example, a slump in output and employment would result in lower prices, wages, and interest rates, which in turn would increase consumer spending, employment, and investment spending. Any excess supply of goods and workers would soon be eliminated.

Classical macroeconomists denied that the level of spending in an economy could be too low to bring about the purchase of the entire full-employment output. They based their denial of inadequate spending in part on *Say's law*, attributed to the nineteenth-century French economist J. B. Say (1767–1832). This law is the disarmingly simple idea that the very act of producing goods generates income equal to the value of the goods produced. The production of any output automatically provides the income needed to buy that output. More succinctly stated, *supply creates its own demand*.

Say's law can best be understood in terms of a barter economy. A woodworker, for example, produces or supplies furniture as a means of buying or demanding the food and clothing produced by other workers. The woodworker's supply of furniture is the income that he will "spend" to satisfy his demand for other goods. The goods he buys (demands) will have a total value exactly equal to the goods he produces (supplies). And so it is for other producers and for the entire economy. Demand must be the same as supply!

Assuming that the composition of output is in accord with consumer preferences,

all markets would be cleared of their outputs. It would seem that all firms need to do to sell a full-employment output is to produce that level of output. Say's law guarantees there will be sufficient spending to purchase it all.

The Great Depression of the 1930s called into question the theory that supply creates its own demand (Say's law). In the United States, real GDP declined by 27 percent and the unemployment rate rocketed to nearly 25 percent. Other nations experienced similar impacts. And cyclical unemployment lingered for a decade. An obvious inconsistency exists between a theory that says that unemployment is virtually impossible and the actual occurrence of a 10-year siege of substantial unemployment.

In 1936 British economist John Maynard Keynes (1883–1946) explained why cyclical unemployment could occur in a market economy. In his *General Theory of Employment, Interest, and*

Money, Keynes attacked the foundations of classical theory and developed the ideas underlying the aggregate expenditures model. Keynes disputed Say's law, pointing out that not all income need be spent in the same period that it is produced. In fact, some income is always saved. In normal times, that saving is borrowed by businesses to buy capital goods—thereby boosting total spending in the economy. But if expectations about the future grow pessimistic, businesses will slash investment spending and a lot of that saving will not be put to use. The result will be insufficient total spending. Unsold goods will accumulate in producers' warehouses, and producers will respond by reducing their output and discharging workers. A recession or depression will result, and widespread cyclical unemployment will occur. Moreover, said Keynes, recessions or depressions are not likely to correct themselves. In contrast to the more laissez-faire view of the classical economists, Keynes argued that government should play an active role in stabilizing the economy.

Nominal GDP will increase because of the higher price level, but real GDP will not.

Application: The Recession of 2007–2009

In December 2007 the U.S. economy entered the longest and one of the deepest recessions since the Great Depression of the 1930s. We will defer discussion of the underlying financial crisis until later chapters, but the ultimate effect of the crisis is easily portrayed through the aggregate expenditures model. We know that the AE_0 line in Figure 31.7a consists of the combined amount of after-tax consumption expenditures (C_a), gross investment expenditures (I_g), net export expenditures (X_n), and government purchases (G) planned at each level of real GDP. During the recession, both after-tax consumption and investment expenditures declined, with planned investment expenditures suffering the largest drop by far.

Aggregate expenditures thus declined, as from AE_0 to AE_1 in Figure 31.7a. This set off a multiple decline in real GDP, illustrated in the figure by the decline from \$510 billion to \$490 billion. In the language of the aggregate expenditures model, a recessionary expenditure gap produced one of the largest negative GDP gaps since the Great Depression. Employment sank by more than 8 million people, and the unemployment rate jumped above 10 percent. As recessions go, this was a big one!

The federal government undertook various Keynesian policies in 2008 and 2009 to try to eliminate the recessionary expenditure gap facing the economy. In 2008, the government provided \$100 billion of tax rebate checks to taxpayers,

hoping that recipients would use most of their checks to buy goods and services. (They didn't! Instead, they used substantial portions of their checks to pay off credit cards and reduce other debt.) In 2009, the federal government enacted a \$787 billion stimulus package designed to boost aggregate expenditures, reduce the recessionary expenditure gap, and, through the multiplier effect, increase real GDP and employment.

We will defer discussion and further assessment of these stimulus attempts until Chapter 33, but Figure 31.7a clearly illuminates their purpose. If the government could drive up aggregate expenditures, such as from AE_1 to AE_0 , the recession would come to an end and the recovery phase of the business cycle would begin.

QUICK REVIEW 31.3

- ✓ Government purchases shift the aggregate expenditures schedule upward and raise equilibrium GDP.
- ✓ Taxes reduce disposable income, lower consumption spending and saving, shift the aggregate expenditures schedule downward, and reduce equilibrium GDP.
- ✓ A recessionary expenditure gap is the amount by which an economy's aggregate expenditures schedule must shift upward to achieve the full-employment GDP; an inflationary expenditure gap is the amount by which the economy's aggregate expenditures schedule must shift downward to achieve full-employment GDP and eliminate demand-pull inflation.

SUMMARY

L031.1 Explain how sticky prices relate to the aggregate expenditures model.

The aggregate expenditures model views the total amount of spending in the economy as the primary factor determining the level of real GDP that the economy will produce. The model assumes that the price level is fixed. Keynes made this assumption to reflect the general circumstances of the Great Depression, in which declines in output and employment, rather than declines in prices, were the dominant adjustments made by firms when they faced huge declines in their sales.

L031.2 Explain how an economy's investment schedule is derived from the investment demand curve and an interest rate.

An investment schedule shows how much investment the firms in an economy are collectively planning to make at each possible level of

GDP. In this chapter, we utilize a simple investment schedule in which investment is a constant value and therefore the same at all levels of GDP. That constant value is derived from the investment demand curve by determining what quantity of investment will be demanded at the economy's current real interest rate.

L031.3 Illustrate how economists combine consumption and investment to depict an aggregate expenditures schedule for a private closed economy and how that schedule can be used to demonstrate the economy's equilibrium level of output (where the total quantity of goods produced equals the total quantity of goods purchased).

For a private closed economy the equilibrium level of GDP occurs when aggregate expenditures and real output are equal or, graphically, where the $C + I_g$ line intersects the 45° line. At any GDP greater than equilibrium GDP, real output will exceed aggregate

spending, resulting in unplanned investment in inventories and eventual declines in output and income (GDP). At any below-equilibrium GDP, aggregate expenditures will exceed real output, resulting in unplanned disinvestment in inventories and eventual increases in GDP.

L031.4 Discuss the two other ways to characterize the equilibrium level of real GDP in a private closed economy: saving = investment and no unplanned changes in inventories.

At equilibrium GDP, the amount households save (leakages) and the amount businesses plan to invest (injections) are equal. Any excess of saving over planned investment will cause a shortage of total spending, forcing GDP to fall. Any excess of planned investment over saving will cause an excess of total spending, inducing GDP to rise. The change in GDP will in both cases correct the discrepancy between saving and planned investment.

At equilibrium GDP, there are no unplanned changes in inventories. When aggregate expenditures diverge from real GDP, an unplanned change in inventories occurs. Unplanned increases in inventories are followed by a cutback in production and a decline of real GDP. Unplanned decreases in inventories result in an increase in production and a rise of GDP.

Actual investment consists of planned investment plus unplanned changes in inventories and is always equal to saving.

L031.5 Analyze how changes in equilibrium real GDP can occur in the aggregate expenditures model and describe how those changes relate to the multiplier.

A shift in the investment schedule (caused by changes in expected rates of return or changes in interest rates) shifts the aggregate expenditures curve and causes a new equilibrium level of real GDP. Real GDP changes by more than the amount of the initial change in investment. This multiplier effect ($\Delta\text{GDP}/\Delta I_g$) accompanies both increases and decreases in aggregate expenditures and also applies to changes in net exports (X_n) and government purchases (G).

L031.6 Explain how economists integrate the international sector (exports and imports) into the aggregate expenditures model.

The net export schedule in the model of the open economy relates net exports (exports minus imports) to levels of real GDP. For simplicity, we assume that the level of net exports is the same at all levels of real GDP.

Positive net exports increase aggregate expenditures to a higher level than they would if the economy were “closed” to international trade. Negative net exports decrease aggregate expenditures relative

to those in a closed economy, decreasing equilibrium real GDP by a multiple of their amount. Increases in exports or decreases in imports have an expansionary effect on real GDP, while decreases in exports or increases in imports have a contractionary effect.

L031.7 Explain how economists integrate the public sector (government expenditures and taxes) into the aggregate expenditures model.

Government purchases in the model of the mixed economy shift the aggregate expenditures schedule upward and raise GDP.

Taxation reduces disposable income, lowers consumption and saving, shifts the aggregate expenditures curve downward, and reduces equilibrium GDP.

In the complete aggregate expenditures model, equilibrium GDP occurs where $C_a + I_g + X_n + G = \text{GDP}$. At the equilibrium GDP, leakages of after-tax saving (S_a), imports (M), and taxes (T) equal injections of investment (I_g), exports (X), and government purchases (G): $S_a + M + T = I_g + X_n + G$. Also, there are no unplanned changes in inventories.

L031.8 Differentiate between equilibrium GDP and full-employment GDP and identify and describe the nature and causes of “recessionary expenditure gaps” and “inflationary expenditure gaps.”

The equilibrium GDP and the full-employment GDP may differ. A recessionary expenditure gap is the amount by which aggregate expenditures at the full-employment GDP fall short of those needed to achieve the full-employment GDP. This gap produces a negative GDP gap (actual GDP minus potential GDP). An inflationary expenditure gap is the amount by which aggregate expenditures at the full-employment GDP exceed those just sufficient to achieve the full-employment GDP. This gap causes demand-pull inflation.

Keynes suggested that the solution to the large negative GDP gap that occurred during the Great Depression was for government to increase aggregate expenditures. It could do this by increasing its own expenditures (G) or by lowering taxes (T) to increase after-tax consumption expenditures (C_a) by households. Because the economy had millions of unemployed workers and massive amounts of unused production capacity, government could boost aggregate expenditures without worrying about creating inflation.

The stuck-price assumption of the aggregate expenditures model is not credible when the economy approaches or attains its full-employment output. With unemployment low and excess production capacity small or nonexistent, an increase in aggregate expenditures will cause inflation along with any increase in real GDP.

- L032.4** Explain the factors that cause changes (shifts) in AS.
- L032.5** Discuss how AD and AS determine an economy's equilibrium price level and level of real GDP.
- L032.6** Describe how the AD-AS model explains periods of demand-pull inflation, cost-push inflation, and recession.
- L032.7** (Appendix) Identify how the aggregate demand curve relates to the aggregate expenditures model.

During the recession of 2007–2009, the economic terms *aggregate demand* and *aggregate supply* moved from the obscurity of economic journals and textbooks to the spotlight of national newspapers, websites, radio, and television.

The media and public asked: Why had *aggregate demand* declined, producing the deepest recession and highest rate of unemployment since 1982? Why hadn't the reductions in interest rates by the Federal Reserve boosted *aggregate demand*? Would the federal government's \$787 billion stimulus package increase *aggregate demand* and reduce unemployment, as intended? Would a resurgence of oil prices and other energy prices reduce *aggregate supply*, choking off an economic expansion?

Aggregate demand and aggregate supply are the featured elements of the **aggregate demand–aggregate supply model (AD-AS model)**, the focus of this chapter. The aggregate expenditures model of the previous chapter is an immediate-short-run model, in which prices are assumed to be fixed. In contrast, the AD-AS model in this chapter is a “variable price–variable output” model that allows both the price level and level of real GDP to change. It can also show longer time horizons, distinguishing

between the immediate short run, the short run, and the long run. Further, in subsequent chapters, we will see that the AD-AS model easily depicts fiscal and monetary

policies such as those used in 2008 and 2009 to try to halt the downward slide of the economy and promote its recovery.

Aggregate Demand

L032.1 Define aggregate demand (AD) and explain how its downward slope is the result of the real-balances effect, the interest-rate effect, and the foreign purchases effect.

Aggregate demand is a schedule or curve that shows the amount of a nation's output (real GDP) that buyers collectively desire to purchase at each possible price level. These buyers include the nation's households, businesses, and government along with consumers located abroad (households, businesses, and governments in other nations). The relationship between the price level (as measured by the GDP price index) and the amount of real GDP demanded is inverse or negative: When the price level rises, the quantity of real GDP demanded decreases; when the price level falls, the quantity of real GDP demanded increases.

Aggregate Demand Curve

The inverse relationship between the price level and real GDP is shown in Figure 32.1, where the aggregate demand curve AD slopes downward, as does the demand curve for an individual product.

Why the downward slope? The explanation is *not* the same as that for why the demand for a single product slopes downward. That explanation centered on the income effect and the substitution effect. When the price of an *individual*

product falls, the consumer's (constant) nominal income allows a larger purchase of the product (the income effect). And, as price falls, the consumer wants to buy more of the product because it becomes relatively less expensive than other goods (the substitution effect).

But these explanations do not work for aggregates. In Figure 32.1, when the economy moves down its aggregate demand curve, it moves to a lower general price level. But our circular flow model tells us that when consumers pay lower prices for goods and services, less nominal income flows to resource suppliers in the form of wages, rents, interest, and profits. As a result, a decline in the price level does not necessarily mean an increase in the nominal income of the economy as a whole. Thus, a decline in the price level need not produce an income effect, where more output is purchased because lower nominal prices leave buyers with greater real income.

Similarly, in Figure 32.1, prices in general are falling as we move down the aggregate demand curve, so the rationale for the substitution effect (where more of a specific product is purchased because it becomes cheaper relative to all other products) is not applicable. There is no *overall* substitution effect among domestically produced goods when the price level falls.

If the conventional substitution and income effects do not explain the downward slope of the aggregate demand curve, what does? The explanation rests on three effects of a price-level change.

FIGURE 32.1 The aggregate demand curve. The downsloping aggregate demand curve AD indicates an inverse (or negative) relationship between the price level and the amount of real output purchased.

Real-Balances Effect A change in the price level produces a **real-balances effect**. Here is how it works: A higher price level reduces the real value or purchasing power of the public's accumulated savings balances. In particular, the real value of assets with fixed money values, such as savings accounts or bonds, diminishes. Because a higher price level erodes the purchasing power of such assets, the public is poorer in real terms and will reduce its spending. A household might buy a new car or a plasma TV if the purchasing power of its financial asset balances is, say, \$50,000. But if inflation erodes the purchasing power of its asset balances to \$30,000, the household may defer its purchase. So a higher price level means less consumption spending.

Interest-Rate Effect The aggregate demand curve also slopes downward because of the **interest-rate effect**. When we draw an aggregate demand curve, we assume that the supply of money in the economy is fixed. But when the price level rises, consumers need more money for purchases and

businesses need more money to meet their payrolls and to buy other resources. A \$10 bill will do when the price of an item is \$10, but a \$10 bill plus a \$1 bill is needed when the item costs \$11. In short, a higher price level increases the demand for money. So, given a fixed supply of money, an increase in money demand will drive up the price paid for its use. That price is the interest rate.

Higher interest rates curtail investment spending and interest-sensitive consumption spending. Firms that expect a 6 percent rate of return on a potential purchase of capital will find that investment potentially profitable when the interest rate is, say, 5 percent. But the investment will be unprofitable and will not be made when the interest rate has risen to 7 percent. Similarly, consumers may decide not to purchase a new house or new automobile when the interest rate on loans goes up. So, by increasing the demand for money and consequently the interest rate, a higher price level reduces the amount of real output demanded.

Foreign Purchases Effect The final reason why the aggregate demand curve slopes downward is the **foreign purchases effect**. When the U.S. price level rises relative to foreign price levels (and exchange rates do not respond quickly or completely), foreigners buy fewer U.S. goods and Americans buy more foreign goods. Therefore, U.S. exports fall and U.S. imports rise. In short, the rise in the price level reduces the quantity of U.S. goods demanded as net exports.

These three effects, of course, work in the opposite direction for a decline in the price level. A decline in the price level increases consumption through the real-balances effect and interest-rate effect, increases investment through the interest-rate effect, and raises net exports by increasing exports and decreasing imports through the foreign purchases effect.

Changes in Aggregate Demand

L032.2 Explain the factors that cause changes (shifts) in AD. Other things equal, a change in the price level will change the amount of aggregate spending and therefore change the amount of real GDP demanded by the economy. Movements along a fixed aggregate demand curve represent these changes in real GDP. However, if one or more of those “other things” change, the entire aggregate demand curve will shift. We call these other things **determinants of aggregate demand** or, less formally, *aggregate demand shifters*. They are listed in Figure 32.2.

Changes in aggregate demand involve two components:

- A change in one of the determinants of aggregate demand that directly changes the amount of real GDP demanded.
- A multiplier effect that produces a greater ultimate change in aggregate demand than the initiating change in spending.

FIGURE 32.2 Changes in aggregate demand. A change in one or more of the listed determinants of aggregate demand will shift the aggregate demand curve. The rightward shift from AD_1 to AD_2 represents an increase in aggregate demand; the leftward shift from AD_1 to AD_3 shows a decrease in aggregate demand. The vertical distances between AD_1 and the dashed lines represent the initial changes in spending. Through the multiplier effect, that spending produces the full shifts of the curves.

Determinants of Aggregate Demand: Factors That Shift the Aggregate Demand Curve

1. Change in consumer spending
 - a. Consumer wealth
 - b. Consumer expectations
 - c. Household borrowing
 - d. Taxes
2. Change in investment spending
 - a. Interest rates
 - b. Expected returns
 - Expected future business conditions
 - Technology
 - Degree of excess capacity
 - Business taxes
3. Change in government spending
4. Change in net export spending
 - a. National income abroad
 - b. Exchange rates

In Figure 32.2, the full rightward shift of the curve from AD_1 to AD_2 shows an increase in aggregate demand, separated into these two components. The horizontal distance between AD_1 and the broken curve to its right illustrates an initial increase in spending, say, \$5 billion of added investment. If the economy's MPC is 0.75, for example, then the simple multiplier is 4. So the aggregate demand curve shifts rightward from AD_1 to AD_2 —four times the distance between AD_1 and the broken line. The multiplier process magnifies the initial change in spending into successive rounds of new consumption spending. After the shift, \$20 billion ($= \5×4) of additional real goods and services are demanded at each price level.

Similarly, the leftward shift of the curve from AD_1 to AD_3 shows a decrease in aggregate demand, the lesser amount of real GDP demanded at each price level. It also involves the initial decline in spending (shown as the horizontal distance between AD_1 and the dashed line to its left), followed by multiplied declines in consumption spending and the ultimate leftward shift to AD_3 .

Let's examine each of the determinants of aggregate demand listed in Figure 32.2.

Consumer Spending

Even when the U.S. price level is constant, domestic consumers may alter their purchases of U.S.-produced real output. If those consumers decide to buy more output at each price level, the aggregate demand curve will shift to the right, as from AD_1 to AD_2 in Figure 32.2. If they decide to buy less output, the aggregate demand curve will shift to the left, as from AD_1 to AD_3 .

Several factors other than a change in the price level may change consumer spending and therefore shift the aggregate demand curve. As Figure 32.2 shows, those factors are real consumer wealth, consumer expectations, household debt, and taxes. Because our discussion here parallels that of Chapter 30, we will be brief.

Consumer Wealth Consumer wealth is the total dollar value of all assets owned by consumers in the economy less the dollar value of their liabilities (debts). Assets include stocks, bonds, and real estate. Liabilities include mortgages, car loans, and credit card balances.

Consumer wealth sometimes changes suddenly and unexpectedly due to surprising changes in asset values. An unforeseen increase in the stock market is a good example. The increase in wealth prompts pleasantly surprised consumers to save less and buy more out of their current incomes than they had previously been planning. The resulting increase in consumer spending—the so-called *wealth effect*—shifts the aggregate demand curve to the right. In contrast, an unexpected decline in asset values will cause an unanticipated reduction in consumer wealth at each price level. As consumers tighten their belts in response to the bad news, a “reverse wealth

effect” sets in. Unpleasantly surprised consumers increase savings and reduce consumption, thereby shifting the aggregate demand curve to the left.

Household Borrowing Consumers can increase their consumption spending by borrowing. Doing so shifts the aggregate demand curve to the right. By contrast, a decrease in borrowing for consumption purposes shifts the aggregate demand curve to the left. The aggregate demand curve will also shift to the left if consumers increase their savings rates to pay off their debts. With more money flowing to debt repayment, consumption expenditures decline and the AD curve shifts left.

Consumer Expectations Changes in expectations about the future may alter consumer spending. When people expect their future real incomes to rise, they tend to spend more of their current incomes. Thus, current consumption spending increases (current saving falls) and the aggregate demand curve shifts to the right. Similarly, a widely held expectation of surging inflation in the near future may increase aggregate demand today because consumers will want to buy products before their prices escalate. Conversely, expectations of lower future income or lower future prices may reduce current consumption and shift the aggregate demand curve to the left.

Personal Taxes A reduction in personal income tax rates raises take-home income and increases consumer purchases at each possible price level. Tax cuts shift the aggregate demand curve to the right. Tax increases reduce consumption spending and shift the curve to the left.

Investment Spending

Investment spending (the purchase of capital goods) is a second major determinant of aggregate demand. A decline in investment spending at each price level will shift the aggregate demand curve to the left. An increase in investment spending will shift it to the right. In Chapter 30 we saw that investment spending depends on the real interest rate and the expected return from investment.

Real Interest Rates Other things equal, an increase in real interest rates will raise borrowing costs, lower investment spending, and reduce aggregate demand. We are not referring here to the “interest-rate effect” that results from a change in the price level. Instead, we are identifying a change in the real interest rate resulting from, say, a change in a nation's money supply. An increase in the money supply lowers the interest rate, thereby increasing investment and aggregate demand. A decrease in the money supply raises the interest rate, reducing investment and decreasing aggregate demand.

Expected Returns Higher expected returns on investment projects will increase the demand for capital goods and shift

the aggregate demand curve to the right. Alternatively, declines in expected returns will decrease investment and shift the curve to the left. Expected returns, in turn, are influenced by several factors:

- **Expectations about future business conditions** If firms are optimistic about future business conditions, they are more likely to forecast high rates of return on current investment and therefore may invest more today. On the other hand, if they think the economy will deteriorate in the future, they will forecast low rates of return and perhaps will invest less today.
- **Technology** New and improved technologies enhance expected returns on investment and thus increase aggregate demand. For example, recent advances in microbiology have motivated pharmaceutical companies to establish new labs and production facilities.
- **Degree of excess capacity** A rise in excess capacity—unused capital—will reduce the expected return on new investment and hence decrease aggregate demand. Other things equal, firms operating factories at well below capacity have little incentive to build new factories. But when firms discover that their excess capacity is dwindling or has completely disappeared, their expected returns on new investment in factories and capital equipment rise. Thus, they increase their investment spending, and the aggregate demand curve shifts to the right.
- **Business taxes** An increase in business taxes will reduce after-tax profits from capital investment and lower expected returns. So investment and aggregate demand will decline. A decrease in business taxes will have the opposite effects.

The variability of interest rates and expected returns makes investment highly volatile. In contrast to consumption, investment spending rises and falls often, independent of changes in total income. Investment, in fact, is the least stable component of aggregate demand.

Government Spending

Government purchases are the third determinant of aggregate demand. An increase in government purchases (for example, more transportation projects) will shift the aggregate demand curve to the right, as long as tax collections and interest rates do not change as a result. In contrast, a reduction in government spending (for example, less military equipment) will shift the curve to the left.

Net Export Spending

The final determinant of aggregate demand is net export spending. Other things equal, higher U.S. *exports* mean an increased foreign demand for U.S. goods. So a rise in net exports (higher exports relative to imports) shifts the aggregate

demand curve to the right. In contrast, a decrease in U.S. net exports shifts the aggregate demand curve leftward. (These changes in net exports are *not* those prompted by a change in the U.S. price level—those associated with the foreign purchases effect. The changes here are shifts of the AD curve, not movements along the AD curve.)

What might cause net exports to change, other than the price level? Two possibilities are changes in national income abroad and changes in exchange rates.

National Income Abroad Rising national income abroad encourages foreigners to buy more products, some of which are made in the United States. U.S. net exports thus rise, and the U.S. aggregate demand curve shifts to the right. Declines in national income abroad do the opposite: They reduce U.S. net exports and shift the U.S. aggregate demand curve to the left.

Exchange Rates Changes in the dollar's exchange rate—the price of foreign currencies in terms of the U.S. dollar—may affect U.S. exports and therefore aggregate demand. Suppose the dollar depreciates in terms of the euro (meaning the euro appreciates in terms of the dollar). The new, relatively lower value of dollars and higher value of euros enables European consumers to obtain more dollars with each euro. From their perspective, U.S. goods are now less expensive; it takes fewer euros to obtain them. So European consumers buy more U.S. goods, and U.S. exports rise. But American consumers can now obtain fewer euros for each dollar. Because they must pay more dollars to buy European goods, Americans reduce their imports. U.S. exports rise and U.S. imports fall. Conclusion: Dollar depreciation increases net exports (imports go down; exports go up) and therefore increases aggregate demand.

Dollar appreciation has the opposite effects: Net exports fall (imports go up; exports go down) and aggregate demand declines.

QUICK REVIEW 32.1

- ✓ Aggregate demand reflects an inverse relationship between the price level and the amount of real output demanded.
- ✓ Changes in the price level create real-balances, interest-rate, and foreign purchases effects that explain the downward slope of the aggregate demand curve.
- ✓ Changes in one or more of the determinants of aggregate demand (Figure 32.2) alter the amounts of real GDP demanded at each price level; they shift the aggregate demand curve. The multiplier effect magnifies initial changes in spending into larger changes in aggregate demand.
- ✓ An increase in aggregate demand is shown as a rightward shift of the aggregate demand curve; a decrease, as a leftward shift of the curve.

Aggregate Supply

L032.3 Define aggregate supply (AS) and explain how it differs in the immediate short run, the short run, and the long run.

Aggregate supply is a schedule or curve showing the relationship between a nation's price level and the amount of real domestic output that firms in the economy produce. This relationship varies depending on the time horizon and how quickly output prices and input prices can change. We will define three time horizons:

- In the *immediate short run*, both input prices as well as output prices are fixed.
- In the *short run*, input prices are fixed, but output prices can vary.
- In the *long run*, input prices as well as output prices can vary.

In Chapter 26, we discussed both the immediate short run and the long run in terms of how an automobile maker named Buzzer Auto responds to changes in the demand for its new car, the Prion. Here we extend the logic of that chapter to the economy as a whole to discuss how total output varies with the price level in the immediate short run, the short run, and the long run. As you will see, the relationship between the price level and total output is different in each of the three time horizons because input prices are stickier than output prices. Although both sets of prices become more flexible as time passes, output prices usually adjust more rapidly.

Aggregate Supply in the Immediate Short Run

Depending on the type of firm, the immediate short run can last anywhere from a few days to a few months. It lasts as long as *both* input prices and output prices stay fixed. Input prices are fixed in both the immediate short run and the short run by contractual agreements. In particular, 75 percent of the average firm's costs are wages and salaries—and these are almost always fixed by labor contracts for months or years at a time. As a result, they are usually fixed for a much longer duration than output prices, which can begin to change within a few days or a few months depending on the type of firm.

That being said, output prices are also typically fixed in the immediate short run. This is most often caused by firms setting fixed prices for their customers and then agreeing to supply whatever quantity demanded results at those fixed prices. For instance, once an appliance manufacturer sets its annual list prices for refrigerators, stoves, ovens, and microwaves, it is obligated to supply however many or few appliances customers want to buy at those prices. Similarly, a catalog company is obligated to sell however much customers want to buy of its products at the prices listed in its current catalog. And it is obligated to supply those quantities demanded until it sends out its next catalog.

With output prices fixed and firms selling however much customers want to purchase at those fixed prices, the **immediate-short-run aggregate supply curve** AS_{ISR} is a horizontal line, as shown in Figure 32.3. The AS_{ISR} curve is horizontal at the overall price level P_1 , which is calculated from all of the individual prices set by the various firms in the economy. Its horizontal shape implies that the total amount of output supplied in the economy depends directly on the volume of spending that results at price level P_1 . If total spending is low at price level P_1 , firms will supply a small amount of output to match the low level of spending. If total spending is high at price level P_1 , they will supply a high level of output to match the high level of spending. The amount of output that results may be higher than or lower than the economy's full-employment output level Q_f .

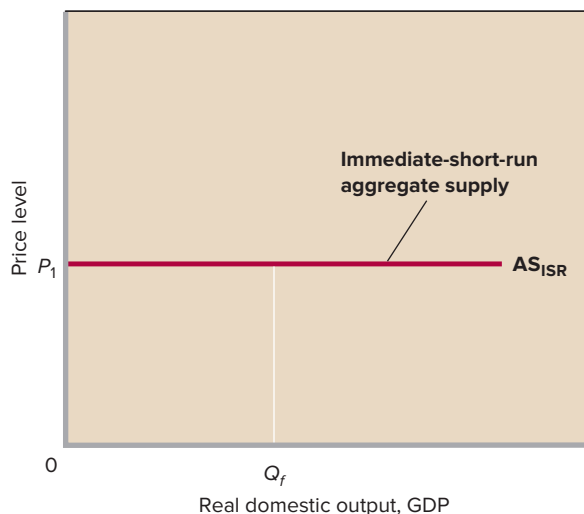

Notice, however, that firms will respond in this manner to changes in total spending only as long as output prices remain fixed. As soon as firms are able to change their product prices, they can respond to changes in aggregate spending not only by increasing or decreasing output but also by raising or lowering prices. This is the situation that leads to the upsloping short-run aggregate supply curve that we discuss next.

Aggregate Supply in the Short Run

The short run begins after the immediate short run ends. As it relates to macroeconomics, the short run is a period of time during which output prices are flexible, but input prices are either totally fixed or highly inflexible.

These assumptions about output prices and input prices are general—they relate to the economy in the aggregate. Naturally, some input prices are more flexible than others.

FIGURE 32.3 Aggregate supply in the immediate short run. In the immediate short run, the aggregate supply curve AS_{ISR} is horizontal at the economy's current price level, P_1 . With output prices fixed, firms collectively supply the level of output that is demanded at those prices.

Since gasoline prices are quite flexible, a package delivery firm like UPS that uses gasoline as an input will have at least one very flexible input price. On the other hand, wages at UPS are set by five-year labor contracts negotiated with its drivers' union, the Teamsters. Because wages are the firm's largest and most important input cost, UPS faces overall input prices that are inflexible for several years at a time. Thus, its "short run"—the period when it can change its shipping prices but not its substantially fixed input prices—is actually quite long. Keep this example in mind as we derive the short-run aggregate supply for the entire economy. Its applicability does not depend on some arbitrary definition of how long the "short run" should be. Instead, the short run for which the model is relevant is any period of time during which output prices are flexible, but input prices are fixed or nearly fixed.

As illustrated in Figure 32.4, the **short-run aggregate supply curve** AS slopes upward because, with input prices fixed, changes in the price level will raise or lower real firm profits. To see how this works, consider an economy that has only a single multiproduct firm called Mega Buzzer and in which the firm's owners must receive a real profit of \$20 to produce the full-employment output of 100 units. Assume the owner's only input (aside from entrepreneurial talent) is 10 units of hired labor at \$8 per worker, for a total wage cost of \$80. Also, assume that the 100 units of output sell for \$1 per unit, so total revenue is \$100. Mega Buzzer's nominal profit is \$20 ($= \$100 - \80), and using the \$1 price to designate the base-price index of 100, its real profit is also \$20 ($= \$20/1.00$). Well and good; the full-employment output is produced.

FIGURE 32.4 The aggregate supply curve (short run). The upsloping aggregate supply curve AS indicates a direct (or positive) relationship between the price level and the amount of real output that firms will offer for sale. The AS curve is relatively flat below the full-employment output because unemployed resources and unused capacity allow firms to respond to price-level rises with large increases in real output. It is relatively steep beyond the full-employment output because resource shortages and capacity limitations make it difficult to expand real output as the price level rises.

Next consider what will happen if the price of Mega Buzzer's output doubles. The doubling of the price level will boost total revenue from \$100 to \$200, but since we are discussing the short run during which input prices are fixed, the \$8 nominal wage for each of the 10 workers will remain unchanged so that total costs stay at \$80. Nominal profit will rise from \$20 ($= \$100 - \80) to \$120 ($= \$200 - \80). Dividing that \$120 profit by the new price index of 200 ($= 2.0$ in hundredths), we find that Mega Buzzer's real profit is now \$60. The rise in the real reward from \$20 to \$60 prompts the firm (economy) to produce more output. Conversely, price-level declines reduce real profits and cause the firm (economy) to reduce its output. So, in the short run, there is a direct, or positive, relationship between the price level and real output. When the price level rises, real output rises and when the price level falls, real output falls. The result is an upsloping short-run aggregate supply curve.

Notice, however, that the upslope of the short-run aggregate supply curve is not constant. It is flatter at outputs below the full-employment output level Q_f and steeper at outputs above it. This has to do with the fact that per-unit production costs underlie the short-run aggregate supply curve. Recall from Chapter 29 that

$$\text{Per-unit production cost} = \frac{\text{total input cost}}{\text{units of output}}$$

The per-unit production cost of any specific level of output establishes that output's price level because the associated price level must cover all the costs of production, including profit "costs."

As the economy expands in the short run, per-unit production costs generally rise because of reduced efficiency. But the extent of that rise depends on where the economy is operating relative to its capacity. When the economy is operating below its full-employment output, it has large amounts of unused machinery and equipment and large numbers of unemployed workers. Firms can put these idle human and property resources back to work with little upward pressure on per-unit production costs. And as output expands, few if any shortages of inputs or production bottlenecks will arise to raise per-unit production costs. That is why the slope of the short-run aggregate supply curve increases only slowly at output levels below the full-employment output level Q_f .

On the other hand, when the economy is operating beyond Q_f , the vast majority of its available resources are already employed. Adding more workers to a relatively fixed number of highly used capital resources such as plant and equipment creates congestion in the workplace and reduces the efficiency (on average) of workers. Adding more capital, given the limited number of available workers, leaves equipment idle and reduces the efficiency of capital. Adding more land resources when capital and labor are highly constrained reduces the efficiency of land resources. Under these circumstances, total

input costs rise more rapidly than total output. The result is rapidly rising per-unit production costs that give the short-run aggregate supply curve its rapidly increasing slope at output levels beyond Q_f .

Aggregate Supply in the Long Run

In macroeconomics, the long run is the time horizon over which both input prices as well as output prices are flexible. It begins after the short run ends. Depending on the type of firm and industry, this may be from a couple of weeks to several years in the future. But for the economy as a whole, it is the time horizon over which all output and input prices—including wage rates—are fully flexible.

The **long-run aggregate supply curve** AS_{LR} is vertical at the economy's full-employment output Q_f , as shown in Figure 32.5. The vertical curve means that in the long run the economy will produce the full-employment output level no matter what the price level is. How can this be? Shouldn't higher prices cause firms to increase output? The explanation lies in the fact that in the long run when both input prices as well as output prices are flexible, profit levels will always adjust to give firms exactly the right profit incentive to produce exactly the full-employment output level, Q_f .

To see why this is true, look back at the short-run aggregate supply curve AS shown in Figure 32.4. Suppose that the economy starts out producing at the full-employment output level Q_f and that the price level at that moment has an index value of $P = 100$. Now suppose that output prices double, so that the price index goes to $P = 200$. We previously demonstrated for our single-firm economy that this doubling of the

price level would cause profits to rise in the short run and that the higher profits would motivate the firm to increase output.

This outcome, however, is totally dependent on the fact that input prices are fixed in the short run. Consider what will happen in the long run when they are free to change. Firms can only produce beyond the full-employment output level by running factories and businesses at extremely high rates. This creates a great deal of demand for the economy's limited supply of productive resources. In particular, labor is in great demand because the only way to produce beyond full employment is if workers are working overtime.

As time passes and input prices are free to change, the high demand will start to raise input prices. In particular, overworked employees will demand and receive raises as employers scramble to deal with the labor shortages that arise when the economy is producing at above its full-employment output level. As input prices increase, firm profits will begin to fall. And as they decline, so does the motive firms have to produce more than the full-employment output level. This process of rising input prices and falling profits continues until the rise in input prices exactly matches the initial change in output prices (in our example, they both double). When that happens, firm profits in real terms return to their original level so that firms are once again motivated to produce at exactly the full-employment output level. This adjustment process means that in the long run the economy will produce at full employment regardless of the price level (in our example, at either $P = 100$ or $P = 200$). That is why the long-run aggregate supply curve AS_{LR} is vertical above the full-employment output level. Every possible price level on the vertical axis is associated with the economy producing at the full-employment output level in the long run once input prices adjust to exactly match changes in output prices.

FIGURE 32.5 Aggregate supply in the long run. The long-run aggregate supply curve AS_{LR} is vertical at the full-employment level of real GDP (Q_f) because in the long run wages and other input prices rise and fall to match changes in the price level. So price-level changes do not affect firms' profits and thus they create no incentive for firms to alter their output.

Focusing on the Short Run

The immediate-short-run aggregate supply curve, the short-run aggregate supply curve, and the long-run aggregate supply curve are all important. Each curve is appropriate to situations that match their respective assumptions about the flexibility of input and output prices. In the remainder of the book, we will have several different opportunities to refer to each curve. But our focus in the rest of this chapter and the several chapters that immediately follow will be on short-run aggregate supply curves, such as the AS curve shown in Figure 32.4. Indeed, unless explicitly stated otherwise, all references to “aggregate supply” are to the AS curve and to aggregate supply in the short run.

Our emphasis on the short-run aggregate supply curve AS stems from our interest in understanding the business cycle in the simplest possible way. It is a fact that real-world economies typically manifest simultaneous changes in both their price levels and their levels of real output. The upsloping

short-run AS curve is the only version of aggregate supply that can handle simultaneous movements in both of these variables. By contrast, the price level is assumed fixed in the immediate-short-run version of aggregate supply illustrated in Figure 32.3 and the economy's output is always equal to the full-employment output level in the long-run version of aggregate supply shown in Figure 32.5. This renders these versions of the aggregate supply curve less useful as part of a core model for analyzing business cycles and demonstrating the short-run government policies designed to deal with them. In our current discussion, we will reserve use of the immediate short run and the long run for specific, clearly identified situations. Later in the book we will explore how the short-run and long-run AS curves are linked, and how that linkage adds several additional insights about business cycles and policy.

Changes in Aggregate Supply

LO32.4 Explain the factors that cause changes (shifts) in AS.

An existing aggregate supply curve identifies the relationship between the price level and real output, other things equal. But when one or more of these other things change, the curve itself shifts. The rightward shift of the curve from AS_1 to AS_2 in Figure 32.6 represents an increase in aggregate supply, indicating that firms are willing to produce and sell more real output at each price level. The leftward shift of the curve from AS_1 to AS_3 represents a decrease in aggregate supply. At each price level, firms produce less output than before.

Figure 32.6 lists the other things that cause a shift of the aggregate supply curve. Called the **determinants of aggregate supply** or *aggregate supply shifters*, they collectively position the aggregate supply curve and shift the curve when they change. Changes in these determinants raise or lower per-unit production costs *at each price level* (or *each level of*

output). These changes in per-unit production cost affect profits, thereby leading firms to alter the amount of output they are willing to produce *at each price level*. For example, firms may collectively offer \$9 trillion of real output at a price level of 1.0 (100 in index value), rather than \$8.8 trillion. Or they may offer \$7.5 trillion rather than \$8 trillion. The point is that when one of the determinants listed in Figure 32.6 changes, the aggregate supply curve shifts to the right or left. Changes that reduce per-unit production costs shift the aggregate supply curve to the right, as from AS_1 to AS_2 ; changes that increase per-unit production costs shift it to the left, as from AS_1 to AS_3 . When per-unit production costs change for reasons other than changes in real output, the aggregate supply curve shifts.

The three aggregate supply determinants listed in Figure 32.6 require more discussion.

Input Prices

Input or resource prices—to be distinguished from the output prices that make up the price level—are a major ingredient of per-unit production costs and therefore a key determinant of aggregate supply. These resources can be either domestic or imported.

Domestic Resource Prices As stated earlier, wages and salaries make up about 75 percent of all business costs. Other things equal, decreases in wages reduce per-unit production costs. So when wages fall, the aggregate supply curve shifts to the right. Increases in wages shift the curve to the left. Examples:

- Labor supply increases because of substantial immigration. Wages and per-unit production costs fall, shifting the AS curve to the right.

FIGURE 32.6 Changes in aggregate supply. A change in one or more of the listed determinants of aggregate supply will shift the aggregate supply curve. The rightward shift of the aggregate supply curve from AS_1 to AS_2 represents an increase in aggregate supply; the leftward shift of the curve from AS_1 to AS_3 shows a decrease in aggregate supply.

Determinants of Aggregate Supply: Factors That Shift the Aggregate Supply Curve

1. Change in input prices
 - a. Domestic resource prices
 - b. Prices of imported resources
2. Change in productivity
3. Change in legal-institutional environment
 - a. Business taxes and subsidies
 - b. Government regulations

- Labor supply decreases because a rapid increase in pension income causes many older workers to opt for early retirement. Wage rates and per-unit production costs rise, shifting the AS curve to the left.

Similarly, the aggregate supply curve shifts when the prices of land and capital inputs change. Examples:

- The price of machinery and equipment falls because of declines in the prices of steel and electronic components. Per-unit production costs decline, and the AS curve shifts to the right.
- The supply of available land resources expands through discoveries of mineral deposits, irrigation of land, or technical innovations that transform “nonresources” (say, vast desert lands) into valuable resources (productive lands). The price of land declines, per-unit production costs fall, and the AS curve shifts to the right.

Prices of Imported Resources Just as foreign demand for U.S. goods contributes to U.S. aggregate demand, resources imported from abroad (such as oil, tin, and copper) add to U.S. aggregate supply. Added supplies of resources—whether domestic or imported—typically reduce per-unit production costs. A decrease in the price of imported resources increases U.S. aggregate supply, while an increase in their price reduces U.S. aggregate supply.

A good example of the major effect that changing resource prices can have on aggregate supply is the oil price hikes of the 1970s. At that time, a group of oil-producing nations called the Organization of Petroleum Exporting Countries (OPEC) worked in concert to decrease oil production in order to raise the price of oil. The 10-fold increase in the price of oil that OPEC achieved during the 1970s drove per-unit production costs up and jolted the U.S. aggregate supply curve leftward. By contrast, a sharp decline in oil prices in the mid-1980s resulted in a rightward shift of the U.S. aggregate supply curve. In 1999 OPEC again reasserted itself, raising oil prices and therefore per-unit production costs for some U.S. producers including airlines and shipping companies like FedEx and UPS. In 2007 the price of oil shot upward, but this increase was attributed to greater demand rather than to decreases in supply caused by OPEC. But keep in mind that no matter what their cause, increases in the price of oil and other resources raise production costs and decrease aggregate supply.

Exchange-rate fluctuations are another factor that may alter the price of imported resources. Suppose that the dollar appreciates, enabling U.S. firms to obtain more foreign currency with each dollar. This means that domestic producers face a lower *dollar* price of imported resources. U.S. firms will respond by increasing their imports of foreign resources, thereby lowering their per-unit production costs at each level of output. Falling per-unit production costs will shift the U.S. aggregate supply curve to the right.

A depreciation of the dollar will have the opposite set of effects and will shift the aggregate supply curve to the left.

Productivity

The second major determinant of aggregate supply is **productivity**, which is a measure of the relationship between a nation’s level of real output and the amount of resources used to produce that output. Productivity is a measure of average real output, or of real output per unit of input:

$$\text{Productivity} = \frac{\text{total output}}{\text{total inputs}}$$

An increase in productivity enables the economy to obtain more real output from its limited resources. An increase in productivity affects aggregate supply by reducing the per-unit cost of output (per-unit production cost). Suppose, for example, that real output is 10 units, that 5 units of input are needed to produce that quantity, and that the price of each input unit is \$2. Then

$$\text{Productivity} = \frac{\text{total output}}{\text{total inputs}} = \frac{10}{5} = 2$$

and

$$\begin{aligned} \text{Per-unit production cost} &= \frac{\text{total input cost}}{\text{total output}} \\ &= \frac{\$2 \times 5}{10} = \$1 \end{aligned}$$

Note that we obtain the total input cost by multiplying the unit input cost by the number of inputs used.

Now suppose productivity increases so that real output doubles to 20 units, while the price and quantity of the input remain constant at \$2 and 5 units. Using the above equations, we see that productivity rises from 2 to 4 and that the per-unit production cost of the output falls from \$1 to \$0.50. The doubled productivity has reduced the per-unit production cost by half.

By reducing the per-unit production cost, an increase in productivity shifts the aggregate supply curve to the right. The main source of productivity advance is improved production technology, often embodied within new plant and equipment that replaces old plant and equipment. Other sources of productivity increases are a better-educated and better-trained workforce, improved forms of business enterprises, and the reallocation of labor resources from lower-productivity to higher-productivity uses.

Much rarer, decreases in productivity increase per-unit production costs and therefore reduce aggregate supply (shift the curve to the left).

Legal-Institutional Environment

Changes in the legal-institutional setting in which businesses operate are the final determinant of aggregate supply. Such changes

may alter the per-unit costs of output and, if so, shift the aggregate supply curve. Two changes of this type are (1) changes in taxes and subsidies and (2) changes in the extent of regulation.

Business Taxes and Subsidies Higher business taxes, such as sales, excise, and payroll taxes, increase per-unit costs and reduce short-run aggregate supply in much the same way as a wage increase does. An increase in such taxes paid by businesses will increase per-unit production costs and shift aggregate supply to the left.

Similarly, a business subsidy—a payment or tax break by government to producers—lowers production costs and increases short-run aggregate supply. For example, the federal government subsidizes firms that blend ethanol (derived from corn) with gasoline to increase the U.S. gasoline supply. This reduces the per-unit production cost of making blended gasoline. To the extent that this and other subsidies are successful, the aggregate supply curve shifts rightward.

Government Regulation It is usually costly for businesses to comply with government regulations. More regulation therefore tends to increase per-unit production costs and shift the aggregate supply curve to the left. “Supply-side” proponents of deregulation of the economy have argued forcefully that, by increasing efficiency and reducing the paperwork associated with complex regulations, deregulation will reduce per-unit costs and shift the aggregate supply curve to the right. Other economists are less certain. Deregulation that results in accounting manipulations, monopolization, and business failures is likely to shift the AS curve to the left rather than to the right.

QUICK REVIEW 32.2

- ✓ The immediate-short-run aggregate supply curve is horizontal; given fixed input and output prices, producers will supply whatever quantity of real output is demanded at the current price level.
- ✓ The short-run aggregate supply curve (or simply the “aggregate supply curve”) is upsloping; given fixed resource prices, higher output prices raise firms’ profits and encourage them to increase their output levels.
- ✓ The long-run aggregate supply curve is vertical; given sufficient time, wages and other input prices rise or fall to match any change in the price level (that is, any change in the level of *output* prices).
- ✓ By altering per-unit production costs independent of changes in the level of output, changes in one or more of the determinants of aggregate supply (Figure 32.6) shift the aggregate supply curve.
- ✓ An increase in short-run aggregate supply is shown as a rightward shift of the aggregate supply curve; a decrease is shown as a leftward shift of the curve.

Equilibrium in the AD-AS Model

L032.5 Discuss how AD and AS determine an economy’s equilibrium price level and level of real GDP.

Of all the possible combinations of price levels and levels of real GDP, which combination will the economy gravitate toward, at least in the short run? **Figure 32.7 (Key Graph)** and its accompanying table provide the answer. Equilibrium occurs at the price level that equalizes the amounts of real output demanded and supplied. The intersection of the aggregate demand curve AD and the aggregate supply curve AS establishes the economy’s **equilibrium price level** and **equilibrium real output**. So aggregate demand and aggregate supply *jointly* establish the price level and level of real GDP.

In Figure 32.7, the equilibrium price level and level of real output are 100 and \$510 billion, respectively. To illustrate why, suppose the price level is 92 rather than 100. We see from the table that the lower price level will encourage businesses to produce real output of \$502 billion. This is shown by point *a* on the AS curve in the graph. But as revealed by the table and point *b* on the aggregate demand curve, buyers will want to purchase \$514 billion of real output at price level 92. Competition among buyers to purchase the lesser available real output of \$502 billion will eliminate the \$12 billion (= \$514 billion – \$502 billion) shortage and pull up the price level to 100.

As the table and graph show, the rise in the price level from 92 to 100 encourages producers to increase their real output from \$502 billion to \$510 billion and causes buyers to scale back their purchases from \$514 billion to \$510 billion. When equality occurs between the amounts of real output produced and purchased, as it does at price level 100, the economy has achieved equilibrium (here, at \$510 billion of real GDP).

A final note: Although the equilibrium price level happens to be 100 in our example, nothing special is implied by that. Any price level can be an equilibrium price level.

Changes in Equilibrium

L032.6 Describe how the AD-AS model explains periods of demand-pull inflation, cost-push inflation, and recession.

Now let’s apply the AD-AS model to various situations that can confront the economy. For simplicity we will use *P* and *Q* symbols, rather than actual numbers. Remember that these symbols represent, respectively, price index values and amounts of real GDP.

Increases in AD: Demand-Pull Inflation

Suppose the economy is operating at its full-employment output and businesses and government decide to increase their spending—actions that shift the aggregate demand curve to the right. Our list of determinants of aggregate demand (Figure 32.2) provides several reasons why this shift might occur. Perhaps

FIGURE 32.7 The equilibrium price level and equilibrium real GDP. The intersection of the aggregate demand curve and the aggregate supply curve determines the economy's equilibrium price level. At the equilibrium price level of 100 (in index-value terms), the \$510 billion of real output demanded matches the \$510 billion of real output supplied. So the equilibrium GDP is \$510 billion.

Real Output Demanded (Billions)	Price Level (Index Number)	Real Output Supplied (Billions)
\$506	108	\$513
508	104	512
510	100	510
512	96	507
514	92	502

QUICK QUIZ FOR FIGURE 32.7

- The AD curve slopes downward because:
 - per-unit production costs fall as real GDP increases.
 - the income and substitution effects are at work.
 - changes in the determinants of AD alter the amounts of real GDP demanded at each price level.
 - decreases in the price level give rise to real-balances effects, interest-rate effects, and foreign purchases effects that increase the amount of real GDP demanded.
- The AS curve slopes upward because:
 - per-unit production costs rise as real GDP expands toward and beyond its full-employment level.
 - the income and substitution effects are at work.
 - changes in the determinants of AS alter the amounts of real GDP supplied at each price level.
 - increases in the price level give rise to real-balances effects, interest-rate effects, and foreign purchases effects that increase the amounts of real GDP supplied.
- At price level 92:
 - a GDP surplus of \$12 billion occurs that drives the price level up to 100.
 - a GDP shortage of \$12 billion occurs that drives the price level up to 100.
 - the aggregate amount of real GDP demanded is less than the aggregate amount of real GDP supplied.
 - the economy is operating beyond its capacity to produce.
- Suppose real output demanded rises by \$4 billion at each price level. The new equilibrium price level will be:
 - 108.
 - 104.
 - 96.
 - 92.

firms boost their investment spending because they anticipate higher future profits from investments in new capital. Those profits are predicated on having new equipment and facilities that incorporate a number of new technologies. And perhaps government increases spending to expand national defense.

As shown by the rise in the price level from P_1 to P_2 in Figure 32.8, the increase in aggregate demand beyond the full-employment level of output causes inflation. This is *demand-pull inflation* because the price level is being pulled up by the increase in aggregate demand. Also, observe that

the increase in demand expands real output from the full-employment level Q_f to Q_1 . The distance between Q_1 and Q_f is a positive, or “inflationary,” GDP gap. Actual GDP exceeds potential GDP.

The classic American example of demand-pull inflation occurred in the late 1960s. The escalation of the war in Vietnam resulted in a 40 percent increase in defense spending between 1965 and 1967 and another 15 percent increase in 1968. The rise in government spending, imposed on an already growing economy, shifted the economy's aggregate

FIGURE 32.8 An increase in aggregate demand that causes demand-pull inflation. The increase of aggregate demand from AD_1 to AD_2 causes demand-pull inflation, shown as the rise in the price level from P_1 to P_2 . It also causes an inflationary GDP gap of Q_1 minus Q_f . The rise of the price level reduces the size of the multiplier effect. If the price level had remained at P_1 , the increase in aggregate demand from AD_1 to AD_2 would increase output from Q_f to Q_2 and the multiplier would have been at full strength. But because of the increase in the price level, real output increases only from Q_f to Q_1 and the multiplier effect is reduced.

demand curve to the right, producing the worst inflation in two decades. Actual GDP exceeded potential GDP, thereby creating an inflationary GDP gap. Inflation jumped from 1.6 percent in 1965 to 5.7 percent by 1970.

A careful examination of Figure 32.8 reveals an interesting point concerning the multiplier effect. The increase in aggregate demand from AD_1 to AD_2 increases real output only to Q_1 , not to Q_2 , because part of the increase in aggregate demand is absorbed as inflation as the price level rises from P_1 to P_2 . Had the price level remained at P_1 , the shift of aggregate demand from AD_1 to AD_2 would have increased real output to Q_2 . The full-strength multiplier effect of Chapters 30 and 31 would have occurred. But in Figure 32.8, inflation reduced the increase in real output—and thus the multiplier effect—by about one-half. For any initial increase in aggregate demand, the resulting increase in real output will be smaller the greater is the increase in the price level. Price-level flexibility weakens the realized multiplier effect.

Decreases in AD: Recession and Cyclical Unemployment

Decreases in aggregate demand describe the opposite end of the business cycle: recession and cyclical unemployment (rather than above-full employment and demand-pull inflation). For example, in 2008 investment spending in the United States greatly declined because of sharply lower expected returns on investment. These lower expectations resulted from

FIGURE 32.9 A decrease in aggregate demand that causes a recession.

If the price level is downwardly inflexible at P_1 , a decline of aggregate demand from AD_1 to AD_2 will move the economy leftward from a to b along the horizontal broken-line segment and reduce real GDP from Q_f to Q_1 . Idle production capacity, cyclical unemployment, and a recessionary GDP gap (of Q_1 minus Q_f) will result. If the price level were flexible downward, the decline in aggregate demand would move the economy depicted from a to c instead of from a to b .

the prospects of poor future business conditions and high degrees of current unused production capacity. In Figure 32.9, we show the resulting decline in aggregate demand as a leftward shift from AD_1 to AD_2 .

But we now add an important twist to the analysis: *Deflation*—a decline in the price level—is not the norm in the American economy. We discussed “sticky prices” in Chapter 26 and previously explained how fixed prices lead to horizontal immediate-short-run aggregate supply curves. For reasons we will examine soon, many important prices in the U.S. economy are downwardly inflexible such that the price level is sticky downward even when aggregate demand substantially declines. Consider Figure 32.9, where the aggregate demand declines from AD_1 to AD_2 . If the price level is stuck at P_1 , the economy moves from a to b along the broken horizontal line rather than from a to c along the short-run aggregate supply curve AS. The outcome is a decline of real output from Q_f to Q_1 , with *no* change in the price level. In this case, it is as if the aggregate supply curve in Figure 32.9 is horizontal at P_1 , to the left of Q_f , as indicated by the dashed line. This decline of real output from Q_f to Q_1 constitutes a *recession*, and since fewer workers are needed to produce the lower output, *cyclical unemployment* arises. The distance between Q_1 and Q_f is a negative, or “recessionary,” GDP gap—the amount by which actual output falls short of potential output.

Close inspection of Figure 32.9 also reveals that without a fall in the price level, the multiplier is at full strength. With the price level stuck at P_1 , real GDP decreases by $Q_f - Q_1$,

which matches the full leftward shift of the AD curve. The multiplier of Chapters 30 and 31 is at full strength when changes in aggregate demand occur along what, in effect, is a horizontal segment of the AS curve. This full-strength multiplier would also exist for an increase in aggregate demand from AD_2 to AD_1 along this broken line, since none of the increase in output would be dissipated as inflation. We will say more about that in Chapter 33.

All recent recessions in the United States have generally mimicked the “GDP gap but no deflation” scenario shown in Figure 32.9. Consider the recession of 2007–2009, which resulted from chaos in the financial markets that quickly led to significant declines in spending by businesses and households. Because of the resulting decline in aggregate demand, real GDP fell short of potential real GDP by roughly \$300 billion in 2008 and \$1 trillion in 2009. The nation’s unemployment rate rose from 4.7 percent in December 2007 to 10.1 percent in October 2009. The price level fell in some months and the rate of inflation declined—meaning that *disinflation* occurred. Considering the full period, however, *deflation* did not occur.

Real output takes the brunt of declines in aggregate demand in the U.S. economy because the price level tends to be downwardly rigid in the immediate short run. There are several reasons for this downward price stickiness.

- **Fear of price wars** Some large firms may be concerned that if they reduce their prices, rivals not only will match their price cuts but may retaliate by making even deeper cuts. An initial price cut may touch off an unwanted *price war*: successively deeper and deeper rounds of price cuts. In such a situation, each firm eventually ends up with far less profit or higher losses than would be the case if each had simply maintained its prices. For this reason, each firm may resist making the initial price cut, choosing instead to reduce production and lay off workers.
- **Menu costs** Firms that think a recession will be relatively short-lived may be reluctant to cut their prices. One reason is what economists metaphorically call **menu costs**, named after their most obvious example: the cost of printing new menus when a restaurant decides to reduce its prices. But lowering prices also creates other costs. Additional costs derive from (1) estimating the magnitude and duration of the shift in demand to determine whether prices should be lowered; (2) repricing items held in inventory; (3) printing and mailing new catalogs; and (4) communicating new prices to customers, perhaps through advertising. When menu costs are present, firms may choose to avoid them by retaining current prices. That is, they may wait to see if the decline in aggregate demand is permanent.

Ratchet Effect

A *ratchet analogy* is a good way to think about the effects of changes in aggregate demand on the price level. A ratchet is a tool or mechanism such as a winch, car jack, or socket wrench that cranks a wheel forward but does not allow it to go backward. Properly set, each allows the operator to move an object (boat, car, or nut) in one direction while preventing it from moving in the opposite direction.

Product prices, wage rates, and per-unit production costs are highly flexible upward when aggregate demand increases along the aggregate supply curve. In the United States, the price level has increased in 60 of the 62 years since 1950.

But when aggregate demand decreases, product prices, wage rates, and per-unit production costs are inflexible downward. The U.S. price level has declined in only two years (1955 and 2009) since 1950, even though aggregate demand and real output have declined in a number of years.

In terms of our analogy, increases in aggregate demand ratchet the U.S. price level upward. Once in place, the higher price level remains until it is ratcheted up again. The higher price level tends to remain even with declines in aggregate demand.

- **Wage contracts** Firms rarely profit from cutting their product prices if they cannot also cut their wage rates. Wages are usually inflexible downward because large parts of the labor force work under contracts prohibiting wage cuts for the duration of the contract. (Collective bargaining agreements in major industries frequently run for 3 years. Similarly, the wages and salaries of nonunion workers are usually adjusted once a year, rather than quarterly or monthly.)
- **Morale, effort, and productivity** Wage inflexibility downward is reinforced by the reluctance of many employers to reduce wage rates. Some current wages may be so-called **efficiency wages**—wages that elicit maximum work effort and thus minimize labor costs per unit of output. If worker productivity (output per hour of work) remains constant, lower wages *do* reduce labor costs per unit of output. But lower wages might impair worker morale and work effort, thereby reducing productivity. Considered alone, lower productivity

raises labor costs per unit of output because less output is produced. If the higher labor costs resulting from reduced productivity exceed the cost savings from the lower wage, then wage cuts will increase rather than reduce labor costs per unit of output. In such situations, firms will resist lowering wages when they are faced with a decline in aggregate demand.

- **Minimum wage** The minimum wage imposes a legal floor under the wages of the least-skilled workers. Firms paying those wages cannot reduce that wage rate when aggregate demand declines.

Decreases in AS: Cost-Push Inflation

Suppose that a major terrorist attack on oil facilities severely disrupts world oil supplies and drives up oil prices by, say, 300 percent. Higher energy prices would spread through the economy, driving up production and distribution costs on a wide variety of goods. The U.S. aggregate supply curve would shift to the left, say, from AS_1 to AS_2 in Figure 32.10. The resulting increase in the price level would be *cost-push inflation*.

The effects of a leftward shift in aggregate supply are doubly bad. When aggregate supply shifts from AS_1 to AS_2 , the economy moves from a to b . The price level rises from P_1 to P_2 and real output declines from Q_f to Q_1 . Along with the cost-push inflation, a recession (and negative GDP gap) occurs. That is exactly what happened in the United States in the mid-1970s when the price of oil rocketed upward. Then, oil expenditures were about 10 percent of U.S. GDP, compared to only 3 percent today. So the U.S. economy is now less vulnerable to cost-push inflation arising from such “aggregate supply shocks.” That said, it is not *immune* from such shocks.

FIGURE 32.10 A decrease in aggregate supply that causes cost-push inflation. A leftward shift of aggregate supply from AS_1 to AS_2 raises the price level from P_1 to P_2 and produces cost-push inflation. Real output declines and a recessionary GDP gap (of Q_1 minus Q_f) occurs.

Increases in AS: Full Employment with Price-Level Stability

Between 1996 and 2000, the United States experienced a combination of full employment, strong economic growth, and very low inflation. Specifically, the unemployment rate fell to 4 percent and real GDP grew nearly 4 percent annually, *without igniting inflation*. At first thought, this “macroeconomic bliss” seems to be incompatible with the AD-AS model. The aggregate supply curve suggests that increases in aggregate demand that are sufficient for over-full employment will raise the price level (see Figure 32.8). Higher inflation, so it would seem, is the inevitable price paid for expanding output beyond the full-employment level.

But inflation remained very mild in the late 1990s. Figure 32.11 helps explain why. Let’s first suppose that aggregate demand increased from AD_1 to AD_2 along aggregate supply curve AS_1 . Taken alone, that increase in aggregate demand would move the economy from a to b . Real output would rise from full-employment output Q_1 to beyond-full-employment output Q_2 . The economy would experience inflation, as shown by the increase in the price level from P_1 to P_3 . Such inflation had occurred at the end of previous vigorous expansions of aggregate demand, including the expansion of the late 1980s.

Between 1990 and 2000, however, larger-than-usual increases in productivity occurred because of a burst of new technology relating to computers, the Internet, inventory management systems, electronic commerce, and so on. We represent this higher-than-usual productivity growth as the

FIGURE 32.11 Growth, full employment, and relative price stability. Normally, an increase in aggregate demand from AD_1 to AD_2 would move the economy from a to b along AS_1 . Real output would expand to Q_2 , and inflation would result (P_1 to P_3). But in the late 1990s, significant increases in productivity shifted the aggregate supply curve, as from AS_1 to AS_2 .

The economy moved from a to c rather than from a to b . It experienced strong economic growth (Q_1 to Q_3), full employment, and only very mild inflation (P_1 to P_2) before receding in March 2001.

LAST WORD

Stimulus and the Great Recession

Aggregate Demand Stimulus Helped to Prevent the 2007–2009 Downturn from Becoming Another Great Depression. But Why Was the Stimulus-Fueled Recovery Substantially Weaker Than Expected?

In retrospect, it is clear that the U.S. economy was in a precarious position in 2006. Trillions of dollars had been borrowed to buy housing on the expectation that home prices would keep on rising. That expectation made borrowing seem like a “no brainer” as a potential buyer could anticipate that if she borrowed \$200,000 to buy a house in one year, she would be able to sell it the next year for, say, \$215,000. Selling at a higher price would allow her to pay off the \$200,000 loan and keep the rest as pure profit.

Unfortunately, home prices started to fall in 2006. When they did, many people who had borrowed to buy houses found themselves unable to pay off their loans. That in turn meant that many banks found themselves holding loans that would never be paid back. Soon, many banks teetered on bankruptcy, the financial markets began to freeze up, and it became clear by late 2007 that the overall economy would probably enter a recession as the result of the housing collapse.

When it was widely recognized in late 2008 that the downturn was going to be unusually severe, public officials took extraordinarily strong steps to stimulate aggregate demand. In terms of monetary policy, the Federal Reserve lowered short-term interest rates to nearly zero in order to shift AD to the right by stimulating investment

rightward shift from AS_1 to AS_2 in Figure 32.11. The relevant aggregate demand and aggregate supply curves thus became AD_2 and AS_2 , not AD_2 and AS_1 . Instead of moving from a to b , the economy moved from a to c . Real output increased from Q_1 to Q_3 , and the price level rose only modestly (from P_1 to P_2). The shift of the aggregate supply curve from AS_1 to AS_2 accommodated the rapid increase in aggregate demand and kept inflation mild. This remarkable combination of rapid productivity growth, rapid real GDP growth, full employment, and relative price-level stability led some observers to proclaim that the United States was experiencing a “new era” or a New Economy.

But in 2001 the New Economy came face-to-face with the old economic principles. Aggregate demand declined because of a substantial fall in investment spending, and in March 2001 the economy experienced a recession. The terrorist attacks of September 11, 2001, further dampened private spending and prolonged the recession throughout 2001. The unemployment rate rose from 4.2 percent in January 2001 to 6 percent in December 2002.

The economy rebounded between 2002 and 2007, eventually reaching its earlier strong economic growth, low inflation, and low unemployment. Some economists began to refer to the period after 1982 as “The Great Moderation” because

and consumption. In terms of fiscal policy, the federal government began the country’s largest peacetime program of deficit-funded spending increases. Those spending increases also shifted AD to the right by increasing the total amount of government expenditures.

recessions were farther apart and relatively mild. They drew the implication that businesses and government had smoothed out the business cycle. Wrong! The severity of the recession of 2007–2009 was a huge surprise to most economists. And so was the weakness of the subsequent recovery, as discussed in this chapter’s Last Word.

QUICK REVIEW 32.3

- ✓ The equilibrium price level and amount of real output are determined at the intersection of the aggregate demand curve and the aggregate supply curve.
- ✓ Increases in aggregate demand beyond the full-employment level of real GDP cause demand-pull inflation.
- ✓ Decreases in aggregate demand cause recessions and cyclical unemployment, partly because the price level and wages tend to be inflexible in a downward direction.
- ✓ Decreases in aggregate supply cause cost-push inflation.
- ✓ Full employment, high economic growth, and price stability are compatible with one another if productivity-driven increases in aggregate supply are sufficient to balance growing aggregate demand.

Those actions were widely credited with preventing a much worse downturn. Real GDP did fall by 4.7 percent and the unemployment rate did rise from 4.6 to 10.1 percent. But those negative changes were much less severe than what had happened during the Great Depression of the 1930s, when real GDP fell by nearly 27 percent and the unemployment rate rose to nearly 25 percent.

As time passed, however, it became clear that the stimulus was having less of an effect than many economists had anticipated. White House economists, for instance, had predicted that the stimulus begun in 2009 would reduce the unemployment rate to 5.2 percent by 2012. But three years later the unemployment rate was still at 8.1 percent despite the Federal Reserve continuing to keep interest rates extremely low and despite the federal government continuing to run massive deficits to fund huge amounts of government expenditures. It took until late 2014 before the unemployment rate fell below 6 percent again.

GDP growth was also disappointing. Real GDP expanded by only 2.4 percent in 2010, 1.8 percent in 2011, and 1.6 percent in 2012. Through the end of 2015, real GDP growth never exceeded 2.5 percent per year. By contrast, the period after the early 1980s recession had seen annual growth rates as high as 7.2 percent per year.

One explanation for the disappointing unemployment and GDP numbers was that it was hard for the stimulus to be very effective given the high debt levels that were built up during the bubble years. The lower interest rates engineered by the Federal Reserve, for instance, were probably not much of an inducement for consumers to increase their borrowing when so many of them were already heavily in debt.

A related problem was that savings rates had risen. When the government attempted to use deficit spending and fiscal policy to stimulate the economy, policymakers were hoping that each dollar of government spending would induce many dollars of consumer spending. But debt-strapped consumers were devoting large parts of their income to making interest payments on debt or paying off loans. So, when stimulus dollars came their way, they often short-circuited the spending process by saving a lot rather than spending a lot.

Another issue was that the stimulus was diffuse while the sectors of the economy in greatest need of stimulus were focused. In particular, the government's stimulus efforts shifted *aggregate* demand to the right. But not all sectors had been hit equally hard by the recession. Thus, when AD shifted right, a lot of the effect was felt in business sectors that hadn't been hurt that badly during the recession. Meanwhile, many sectors that had been hit hard only received a small portion of the total amount of stimulus that they would have needed to see a full recovery.

A related problem was that in some sectors of the economy, the government's stimulus may have resulted mostly in price increases rather than output gains. That is because the supply curves for many industries are steep. Consider dentists and jewelers. It takes many years to train competent dentists or skilled jewelers. So even if the demand for their services shifts right, there is a nearly fixed supply of dental services and jewelry services in the short run—meaning that any increase in demand will mostly cause higher prices rather than higher output. So when the government shifted *aggregate* demand to the right, certain sectors probably saw mostly price increases rather than output gains.

SUMMARY

L032.1 Define aggregate demand (AD) and explain how its downward slope is the result of the real-balances effect, the interest-rate effect, and the foreign purchases effect.

The aggregate demand–aggregate supply model (AD-AS model) is a flexible-price model that enables analysis of simultaneous changes of real GDP and the price level.

The aggregate demand curve shows the level of real output that the economy demands at each price level.

The aggregate demand curve is downsloping because of the real-balances effect, the interest-rate effect, and the foreign purchases effect. The real-balances effect indicates that inflation reduces the real value or purchasing power of fixed-value financial assets held by households, causing cutbacks in consumer spending. The interest-rate effect means that, with a specific supply of money, a higher price level increases the demand for money, thereby raising the interest rate and reducing investment purchases. The foreign purchases effect suggests that an increase in one country's price level relative to the price levels in other countries reduces the net export component of that nation's aggregate demand.

L032.2 Explain the factors that cause changes (shifts) in AD.

The determinants of aggregate demand consist of spending by domestic consumers, by businesses, by government, and by foreign buyers. Changes in the factors listed in Figure 32.2 alter the spending by these groups and shift the aggregate demand curve. The extent of the shift is determined by the size of the initial change in spending and the strength of the economy's multiplier.

L032.3 Define aggregate supply (AS) and explain how it differs in the immediate short run, the short run, and the long run.

The aggregate supply curve shows the levels of real output that businesses will produce at various possible price levels. The slope of the aggregate supply curve depends upon the flexibility of input and output prices. Since these vary over time, aggregate supply curves are categorized into three time horizons, each having different underlying assumptions about the flexibility of input and output prices.

The *immediate-short-run aggregate supply curve* assumes that both input prices and output prices are fixed. With output prices

fixed, the aggregate supply curve is a horizontal line at the current price level. The *short-run aggregate supply curve* assumes nominal wages and other input prices remain fixed while output prices vary. The aggregate supply curve is generally upsloping because per-unit production costs, and hence the prices that firms must receive, rise as real output expands. The aggregate supply curve is relatively steep to the right of the full-employment output level and relatively flat to the left of it. The *long-run aggregate supply curve* assumes that nominal wages and other input prices fully match any change in the price level. The curve is vertical at the full-employment output level.

Because the short-run aggregate supply curve is the only version of aggregate supply that can handle simultaneous changes in the price level and real output, it serves well as the core aggregate supply curve for analyzing the business cycle and economic policy. Unless stated otherwise, all references to “aggregate supply” refer to short-run aggregate supply and the short-run aggregate supply curve.

L032.4 Explain the factors that cause changes (shifts) in AS.

Figure 32.6 lists the determinants of aggregate supply: input prices, productivity, and the legal-institutional environment. A change in any one of these factors will change per-unit production costs at each level of output and therefore will shift the aggregate supply curve.

L032.5 Discuss how AD and AS determine an economy's equilibrium price level and level of real GDP.

The intersection of the aggregate demand and aggregate supply curves determines an economy's equilibrium price level and real

GDP. At the intersection, the quantity of real GDP demanded equals the quantity of real GDP supplied.

L032.6 Describe how the AD-AS model explains periods of demand-pull inflation, cost-push inflation, and recession.

Increases in aggregate demand to the right of the full-employment output cause inflation and positive GDP gaps (actual GDP exceeds potential GDP). An upsloping aggregate supply curve weakens the multiplier effect of an increase in aggregate demand because a portion of the increase in aggregate demand is dissipated in inflation.

Shifts of the aggregate demand curve to the left of the full-employment output cause recession, negative GDP gaps, and cyclical unemployment. The price level may not fall during recessions because of downwardly inflexible prices and wages. This inflexibility results from fear of price wars, menu costs, wage contracts, efficiency wages, and minimum wages. When the price level is fixed, changes in aggregate demand produce full-strength multiplier effects.

Leftward shifts of the aggregate supply curve reflect increases in per-unit production costs and cause cost-push inflation, with accompanying negative GDP gaps.

Rightward shifts of the aggregate supply curve, caused by large improvements in productivity, help explain the simultaneous achievement of full employment, economic growth, and price stability that occurred in the United States between 1996 and 2000. The recession of 2001, however, ended the expansionary phase of the business cycle. Expansion resumed in the 2002–2007 period, before giving way to the severe recession of 2007–2009. The subsequent recovery was unexpectedly slow despite major amounts of monetary and fiscal stimuli.

DISCUSSION QUESTIONS

- Why is the aggregate demand curve downsloping? Specify how your explanation differs from the explanation for the downsloping demand curve for a single product. What role does the multiplier play in shifts of the aggregate demand curve? **L032.1**
- Distinguish between “real-balances effect” and “wealth effect,” as the terms are used in this chapter. How does each relate to the aggregate demand curve? **L032.1**
- What assumptions cause the immediate-short-run aggregate supply curve to be horizontal? Why is the long-run aggregate supply curve vertical? Explain the shape of the short-run aggregate supply curve. Why is the short-run aggregate supply curve relatively flat to the left of the full-employment output and relatively steep to the right? **L032.3**
- Explain how an upsloping aggregate supply curve weakens the realized multiplier effect from an initial change in investment spending. **L032.6**
- Why does a reduction in aggregate demand in the actual economy reduce real output, rather than the price level? Why might a full-strength multiplier apply to a decrease in aggregate demand? **L032.6**
- Explain: “Unemployment can be caused by a decrease of aggregate demand or a decrease of aggregate supply.” In each case, specify the price-level outcomes. **L032.6**

7. Use shifts of the AD and AS curves to explain (a) the U.S. experience of strong economic growth, full employment, and price stability in the late 1990s and early 2000s and (b) how a strong negative wealth effect from, say, a precipitous drop in house prices could cause a recession even though productivity is surging. **L032.6**
8. In early 2001 investment spending sharply declined in the United States. In the two months following the September 11,

2001, attacks on the United States, consumption also declined. Use AD-AS analysis to show the two impacts on real GDP. **L032.6**

REVIEW QUESTIONS

1. Which of the following help to explain why the aggregate demand curve slopes downward? **L032.1**
 - a. When the domestic price level rises, our goods and services become more expensive to foreigners.
 - b. When government spending rises, the price level falls.
 - c. There is an inverse relationship between consumer expectations and personal taxes.
 - d. When the price level rises, the real value of financial assets (like stocks, bonds, and savings account balances) declines.
2. Which of the following will shift the aggregate demand curve to the left? **L032.2**
 - a. The government reduces personal income taxes.
 - b. Interest rates rise.
 - c. The government raises corporate profit taxes.
 - d. There is an economic boom overseas that raises the incomes of foreign households.
3. Label each of the following descriptions as being either an immediate-short-run aggregate supply curve, a short-run aggregate supply curve, or a long-run aggregate supply curve. **L032.3**
 - a. A vertical line.
 - b. The price level is fixed.
 - c. Output prices are flexible, but input prices are fixed.
 - d. A horizontal line.
 - e. An upsloping curve.
 - f. Output is fixed.
4. Which of the following will shift the aggregate supply curve to the right? **L032.4**
 - a. A new networking technology increases productivity all over the economy.
 - b. The price of oil rises substantially.
 - c. Business taxes fall.
 - d. The government passes a law doubling all manufacturing wages.
5. At the current price level, producers supply \$375 billion of final goods and services while consumers purchase \$355 billion of final goods and services. The price level is: **L032.5**
 - a. Above equilibrium.
 - b. At equilibrium.
 - c. Below equilibrium.
 - d. More information is needed.
6. What effects would each of the following have on aggregate demand or aggregate supply, other things equal? In each case, use a diagram to show the expected effects on the equilibrium price level and the level of real output, assuming that the price level is flexible both upward and downward. **L032.5**
 - a. A widespread fear by consumers of an impending economic depression.
 - b. A new national tax on producers based on the value added between the costs of the inputs and the revenue received from their output.
 - c. A reduction in interest rates at each price level.
 - d. A major increase in spending for health care by the federal government.
 - e. The general expectation of coming rapid inflation.
 - f. The complete disintegration of OPEC, causing oil prices to fall by one-half.
 - g. A 10 percent across-the-board reduction in personal income tax rates.
 - h. A sizable increase in labor productivity (with no change in nominal wages).
 - i. A 12 percent increase in nominal wages (with no change in productivity).
 - j. An increase in exports that exceeds an increase in imports (not due to tariffs).
7. True or False: Decreases in AD normally lead to decreases in both output and the price level. **L032.6**
8. Assume that (a) the price level is flexible upward but not downward and (b) the economy is currently operating at its full-employment output. Other things equal, how will each of the following affect the equilibrium price level and equilibrium level of real output in the short run? **L032.6**
 - a. An increase in aggregate demand.
 - b. A decrease in aggregate supply, with no change in aggregate demand.
 - c. Equal increases in aggregate demand and aggregate supply.
 - d. A decrease in aggregate demand.
 - e. An increase in aggregate demand that exceeds an increase in aggregate supply.
9. True or False: If the price of oil suddenly increases by a large amount, AS will shift left, but the price level will not rise thanks to price inflexibility. **L032.6**

PROBLEMS

1. Suppose that consumer spending initially rises by \$5 billion for every 1 percent rise in household wealth and that investment spending initially rises by \$20 billion for every 1 percentage point fall in the real interest rate. Also assume that the economy's multiplier is 4. If household wealth falls by 5 percent

because of declining house values, and the real interest rate falls by 2 percentage points, in what direction and by how much will the aggregate demand curve initially shift at each price level? In what direction and by how much will it eventually shift? **L032.2**

2. Answer the following questions on the basis of the following three sets of data for the country of North Vaudeville: **L032.4**

(A)		(B)		(C)	
Price Level	Real GDP	Price Level	Real GDP	Price Level	Real GDP
110	275	100	200	110	225
100	250	100	225	100	225
95	225	100	250	95	225
90	200	100	275	90	225

- a. Which set of data illustrates aggregate supply in the immediate short run in North Vaudeville? The short run? The long run?
- b. Assuming no change in hours of work, if real output per hour of work increases by 10 percent, what will be the new levels of real GDP in the right column of A? Do the new data reflect an increase in aggregate supply or do they indicate a decrease in aggregate supply?
3. Suppose that the aggregate demand and aggregate supply schedules for a hypothetical economy are as shown in the following table. **L032.5**

Amount of Real GDP Demanded, Billions	Price Level (Price Index)	Amount of Real GDP Supplied, Billions
\$100	300	\$450
200	250	400
300	200	300
400	150	200
500	100	100

- a. Use the data above to graph the aggregate demand and aggregate supply curves. What are the equilibrium price level and the equilibrium level of real output in this hypothetical economy? Is the equilibrium real output also necessarily the full-employment real output?
- b. If the price level in this economy is 150, will quantity demanded equal, exceed, or fall short of quantity supplied? By what amount? If the price level is 250, will quantity

demanded equal, exceed, or fall short of quantity supplied? By what amount?

- c. Suppose that buyers desire to purchase \$200 billion of extra real output at each price level. Sketch in the new aggregate demand curve as AD_1 . What are the new equilibrium price level and level of real output?
4. Suppose that the table presented below shows an economy's relationship between real output and the inputs needed to produce that output: **L032.4**

Input Quantity	Real GDP
150.0	\$400
112.5	300
75.0	200

- a. What is productivity in this economy?
- b. What is the per-unit cost of production if the price of each input unit is \$2?
- c. Assume that the input price increases from \$2 to \$3 with no accompanying change in productivity. What is the new per-unit cost of production? In what direction would the \$1 increase in input price push the economy's aggregate supply curve? What effect would this shift of aggregate supply have on the price level and the level of real output?
- d. Suppose that the increase in input price does not occur but, instead, that productivity increases by 100 percent. What would be the new per-unit cost of production? What effect would this change in per-unit production cost have on the economy's aggregate supply curve? What effect would this shift of aggregate supply have on the price level and the level of real output?
5. Refer to the data in the table that accompanies problem 2. Suppose that the present equilibrium price level and level of real GDP are 100 and \$225, and that data set B represents the relevant aggregate supply schedule for the economy. **L032.6**
- a. What must be the current amount of real output demanded at the 100 price level?
- b. If the amount of output demanded declined by \$25 at the 100 price levels shown in B, what would be the new equilibrium real GDP? In business cycle terminology, what would economists call this change in real GDP?

The Relationship of the Aggregate Demand Curve to the Aggregate Expenditures Model*

L032.7 Identify how the aggregate demand curve relates to the aggregate expenditures model.

The aggregate demand curve of this chapter and the aggregate expenditures model of Chapter 31 are intricately related.

Derivation of the Aggregate Demand Curve from the Aggregate Expenditures Model

We can directly connect the downsloping aggregate demand curve to the aggregate expenditures model by relating various possible price levels to corresponding equilibrium GDPs. In Figure 1 we have stacked the aggregate expenditures model (Figure 1a) and the aggregate demand curve (Figure 1b) vertically. This is possible because the horizontal axes of both models measure real GDP. Now let's derive the AD curve in three distinct steps. (Throughout this discussion, keep in mind that price level P_1 is lower than price level P_2 , which is lower than price level P_3 .)

- First suppose that the economy's price level is P_1 and its aggregate expenditures schedule is AE_1 , the top schedule in Figure 1a. The equilibrium GDP is then Q_1 at point 1. So, in Figure 1b, we can plot the equilibrium real output Q_1 and the corresponding price level P_1 . This gives us point 1' in Figure 1b.
- Now assume the price level rises from P_1 to P_2 . Other things equal, this higher price level will (1) decrease the value of real balances (wealth), decreasing consumption expenditures; (2) increase the interest rate, reducing investment and interest-sensitive consumption expenditures; and (3) increase imports and decrease exports, reducing net export

FIGURE 1 Deriving the aggregate demand curve from the aggregate expenditures model. (a) Rising price levels from P_1 to P_2 to P_3 shift the aggregate expenditures curve downward from AE_1 to AE_2 to AE_3 and reduce real GDP from Q_1 to Q_2 to Q_3 . (b) The aggregate demand curve AD is derived by plotting the successively lower real GDPs from the upper graph against the P_1 , P_2 , and P_3 price levels.

*This appendix presumes knowledge of the aggregate expenditures model discussed in Chapter 31 and should be skipped if Chapter 31 was not assigned.

expenditures. The aggregate expenditures schedule will fall from AE_1 to, say, AE_2 in Figure 1a, giving us equilibrium Q_2 at point 2. In Figure 1b we plot this new price-level–real-output combination, P_2 and Q_2 , as point 2'.

- Finally, suppose the price level rises from P_2 to P_3 . The value of real balances falls, the interest rate rises, exports fall, and imports rise. Consequently, the consumption, investment, and net export schedules fall, shifting the aggregate expenditures schedule downward from AE_2 to AE_3 , which gives us equilibrium Q_3 at point 3. In Figure 1b, this enables us to locate point 3', where the price level is P_3 and real output is Q_3 .

In summary, increases in the economy's price level will successively shift its aggregate expenditures schedule downward and will reduce real GDP. The resulting price-level–real-GDP combinations will yield various points such as 1', 2', and 3' in Figure 1b. Together, such points locate the downsloping aggregate demand curve for the economy.

Aggregate Demand Shifts and the Aggregate Expenditures Model

The determinants of aggregate demand listed in Figure 32.2 are the components of the aggregate expenditures model discussed in Chapter 31. When one of the determinants of aggregate demand changes, the aggregate expenditures schedule shifts upward or downward. We can easily link such shifts of the aggregate expenditures schedule to shifts of the aggregate demand curve.

Let's suppose that the price level is constant. In Figure 2 we begin with the aggregate expenditures schedule at AE_1 in the top diagram, yielding equilibrium real output Q_1 . Assume now that investment increases in response to more optimistic business expectations, so the aggregate expenditures schedule rises from AE_1 to AE_2 . (The notation "at P_1 " reminds us that the price level is assumed constant.) The result will be a multiplied increase in equilibrium real output from Q_1 to Q_2 .

In Figure 2b the increase in investment spending is reflected in the horizontal distance between AD_1 and the broken curve to its right. The immediate effect of the increase in investment is an increase in aggregate demand by the exact amount of the new spending. But then the multiplier process magnifies the initial increase in investment into successive rounds of consumption spending and an ultimate multiplied increase in aggregate demand from AD_1 to AD_2 . Equilibrium

FIGURE 2 Shifts of the aggregate expenditures schedule and of the aggregate demand curve. (a) A change in some determinant of consumption, investment, or net exports (other than the price level) shifts the aggregate expenditures schedule upward from AE_1 to AE_2 . The multiplier increases real output from Q_1 to Q_2 . (b) The counterpart of this change is an initial rightward shift of the aggregate demand curve by the amount of initial new spending (from AD_1 to the broken curve). This leads to a multiplied rightward shift of the curve to AD_2 , which is just sufficient to show the same increase of real output as that in the aggregate expenditures model.

real output rises from Q_1 to Q_2 , the same multiplied increase in real GDP as that in the top graph. The initial increase in investment in the top graph has shifted the AD curve in the lower graph by a horizontal distance equal to the change in investment times the multiplier. This particular change in real GDP is still associated with the constant price level P_1 . To generalize,

$$\text{Shift of AD curve} = \text{initial change in spending} \times \text{multiplier}$$

APPENDIX SUMMARY

L032.7 Identify how the aggregate demand curve relates to the aggregate expenditures model.

A change in the price level alters the location of the aggregate expenditures schedule through the real-balances, interest-rate, and foreign purchases effects. The aggregate demand curve is derived from the aggregate expenditures model by allowing the price level to

change and observing the effect on the aggregate expenditures schedule and thus on equilibrium GDP.

With the price level held constant, increases in consumption, investment, government, and net export expenditures shift the aggregate expenditures schedule upward and the aggregate demand curve to the right. Decreases in these spending components produce the opposite effects.

APPENDIX PROBLEMS

1. Refer to Figures 1a and 1b in the Appendix. Assume that Q_1 is 300, Q_2 is 200, Q_3 is 100, P_3 is 120, P_2 is 100, and P_1 is 80. If the price level increases from P_1 to P_3 in figure 1b, in what direction and by how much will real GDP change? If the slopes of the AE lines in Figure 1a are 0.8 and equal to the MPC, in what direction will the aggregate expenditures schedule in Figure 1a need to shift to produce the previously determined change in real GDP? What is the size of the multiplier in this example? **L032.7**
2. Refer to Figure 2 in the Appendix and assume that Q_1 is \$400 and Q_2 is \$500, the price level is stuck at P_1 , and the slopes of the AE lines in Figure 2a are 0.75 and equal to the MPC. In what direction and by how much does the aggregate expenditures schedule in Figure 2a need to shift to move the aggregate demand curve in Figure 2b from AD_1 to AD_2 ? What is the multiplier in this example? Given the multiplier, what must be the distance between AD_1 and the broken line to its right at P_1 ? **L032.7**

Fiscal Policy, Deficits, and Debt

Learning Objectives

- L033.1** Identify and explain the purposes, tools, and limitations of fiscal policy.
- L033.2** Explain the role of built-in stabilizers in moderating business cycles.
- L033.3** Describe how the cyclically adjusted budget reveals the status of U.S. fiscal policy.
- L033.4** Summarize recent U.S. fiscal policy and the projections for U.S. fiscal policy over the next few years.
- L033.5** Discuss the problems that governments may encounter in enacting and applying fiscal policy.
- L033.6** Discuss the size, composition, and consequences of the U.S. public debt.

In the previous chapter we saw that an excessive increase in aggregate demand can cause demand-pull inflation and that a significant decline in aggregate demand can cause recession and cyclical unemployment. For these reasons, the federal government sometimes uses budgetary actions to try

to “stimulate the economy” or “rein in inflation.” Such counter-cyclical **fiscal policy** consists of deliberate changes in government spending and tax collections designed to achieve full employment, control inflation, and encourage economic growth. (The adjective “fiscal” simply means “financial.”)

We begin this chapter by examining the logic behind fiscal policy, its current status, and its limitations. Then we examine a closely related topic: the U.S. public debt.

Our discussion of fiscal policy and public debt is very timely. In 2009, Congress and the Obama administration began a \$787 billion stimulus program designed to help lift the U.S. economy out of deep recession. This fiscal policy contributed to a \$1.4 trillion federal budget deficit in 2009, which increased the size of the U.S. public debt to \$11.9 trillion. Large deficits continued in subsequent years, so that the U.S. public debt passed \$19.0 trillion in 2016.

Fiscal Policy and the AD-AS Model

L033.1 Identify and explain the purposes, tools, and limitations of fiscal policy.

The fiscal policy just defined is *discretionary* (or “active”). It is often initiated on the advice of the president’s **Council of Economic Advisers (CEA)**, a group of three economists

appointed by the president to provide expertise and assistance on economic matters. Discretionary changes in government spending and taxes are *at the option* of the federal government. They do not occur automatically. Changes that occur without congressional action are *nondiscretionary* (or “passive” or “automatic”), and we will examine them later in this chapter.

Expansionary Fiscal Policy

When recession occurs, an **expansionary fiscal policy** may be in order. This policy consists of government spending increases, tax reductions, or both, designed to increase aggregate demand and therefore raise real GDP. Consider Figure 33.1, where we suppose that a sharp decline in investment spending has shifted the economy’s aggregate demand curve to the left from AD_1 to AD_2 . (Disregard the arrows and dashed downsloping line for now.) The cause of the recession may be that profit expectations on investment projects have dimmed, curtailing investment spending and reducing aggregate demand.

Suppose the economy’s potential or full-employment output is \$510 billion in Figure 33.1. If the price level is inflexible downward at P_1 , the broken horizontal line becomes relevant to the analysis. The aggregate demand curve moves leftward and reduces real GDP from \$510 billion to \$490 billion. A negative GDP gap of \$20 billion ($= \$490 \text{ billion} - \510 billion) arises. An increase in unemployment accompanies this negative GDP gap because fewer workers are needed to produce the reduced output. In short, the economy depicted is suffering both recession and cyclical unemployment.

What fiscal policy should the federal government adopt to try to stimulate the economy? It has three main options: (1) increase government spending, (2) reduce taxes, or (3) use some combination of the two. If the federal budget is balanced at the outset, expansionary fiscal policy will create a government **budget deficit**—government spending in excess of tax revenues.

Increased Government Spending Other things equal, a sufficient increase in government spending will shift an economy’s aggregate demand curve to the right, from AD_2 to AD_1 in Figure 33.1. To see why, suppose that the recession prompts the government to initiate \$5 billion of new spending on highways, education, and health care. We represent this new \$5 billion of government spending as the horizontal distance between AD_2 and the dashed downsloping line immediately to its right. At each price level, the amount of real output that is demanded is now \$5 billion greater than that demanded before the expansion of government spending.

But the initial increase in aggregate demand is not the end of the story. Through the multiplier effect, the aggregate demand curve shifts to AD_1 , a distance that exceeds that represented by the originating \$5 billion increase in government purchases. This greater shift occurs because the multiplier process magnifies the initial change in spending into successive rounds of new consumption spending. If the economy’s MPC is 0.75, then the simple multiplier is 4. So the aggregate demand curve shifts rightward by four times the distance between AD_2 and the broken downsloping line. Because this *particular* increase in aggregate demand occurs along the horizontal broken-line segment, real output rises by the full extent of the multiplier. Observe that real output rises to \$510 billion, up \$20 billion from its recessionary level of \$490 billion. Concurrently, unemployment falls as firms increase their employment to the full-employment level that existed before the recession.

Tax Reductions Alternatively, the government could reduce taxes to shift the aggregate demand curve rightward, as from AD_2 to AD_1 . Suppose the government cuts personal income taxes by \$6.67 billion, which increases disposable income by the same amount. Consumption will rise by \$5 billion ($= \text{MPC of } 0.75 \times \6.67 billion) and saving will go up by \$1.67 billion ($= \text{MPS of } 0.25 \times \6.67 billion). In this case

FIGURE 33.1 Expansionary fiscal policy. Expansionary fiscal policy uses increases in government spending or tax cuts to push the economy out of recession. In an economy with an MPC of 0.75, a \$5 billion increase in government spending or a \$6.67 billion decrease in personal taxes (producing a \$5 billion initial increase in consumption) expands aggregate demand from AD_2 to the downsloping dashed curve. The multiplier then magnifies this initial increase in spending to AD_1 . So real GDP rises along the broken horizontal line by \$20 billion.

the horizontal distance between AD_2 and the dashed downsloping line in Figure 33.1 represents only the \$5 billion initial increase in consumption spending. Again, we call it “initial” consumption spending because the multiplier process yields successive rounds of increased consumption spending. The aggregate demand curve eventually shifts rightward by four times the \$5 billion initial increase in consumption produced by the tax cut. Real GDP rises by \$20 billion, from \$490 billion to \$510 billion, implying a multiplier of 4. Employment increases accordingly.

You may have noted that a tax cut must be somewhat larger than the proposed increase in government spending if it is to achieve the same amount of rightward shift in the aggregate demand curve. This is because part of a tax reduction increases saving, rather than consumption. To increase initial consumption by a specific amount, the government must reduce taxes by more than that amount. With an MPC of 0.75, taxes must fall by \$6.67 billion for \$5 billion of new consumption to be forthcoming because \$1.67 billion is saved (not consumed). If the MPC had instead been, say, 0.6, an \$8.33 billion reduction in tax collections would have been necessary to increase initial consumption by \$5 billion. The smaller the MPC, the greater the tax cut needed to accomplish a specific initial increase in consumption and a specific shift in the aggregate demand curve.

Combined Government Spending Increases and Tax Reductions The government may combine spending increases and tax cuts to produce the desired initial increase in spending and the eventual increase in aggregate demand and real GDP. In the economy depicted in Figure 33.1, the government might increase its spending by \$1.25 billion while reducing taxes by \$5 billion. As an exercise, you should explain why this combination will produce the targeted \$5 billion initial increase in new spending.

If you were assigned Chapter 31, think through these three fiscal policy options in terms of the recessionary-expenditure-gap analysis associated with the aggregate expenditures model (Figure 31.7). And recall from the appendix to Chapter 32 that rightward shifts of the aggregate demand curve relate directly to upward shifts of the aggregate expenditures schedule.

Contractionary Fiscal Policy

When demand-pull inflation occurs, a restrictive or **contractionary fiscal policy** may help control it. This policy consists of government spending reductions, tax increases, or both, designed to decrease aggregate demand and therefore lower or eliminate inflation. Look at Figure 33.2, where the full-employment level of real GDP is \$510 billion. The economy starts at equilibrium at point a , where the initial aggregate demand curve AD_3 intersects aggregate supply curve AS . Suppose that after going through the multiplier process, a \$5 billion initial increase in investment and net export spending shifts the aggregate demand curve to the right by \$20 billion, from AD_3 to AD_4 . (Ignore the downsloping dashed line for now.) Given the upsloping AS curve, however, the equilibrium GDP does not rise by the full \$20 billion. It only rises by \$12 billion, to \$522 billion, thereby creating an inflationary GDP gap of \$12 billion (\$522 billion – \$510 billion). The upslope of the AS curve means that some of the rightward movement of the AD curve ends up causing demand-pull inflation rather than increased output. As a result, the price level rises from P_1 to P_2 and the equilibrium moves to point b .

Without a government response, the inflationary GDP gap will cause further inflation (as input prices rise in the long run to meet the increase in output prices). If the government looks to fiscal policy to eliminate the inflationary GDP gap, its options are the opposite of those used to combat recession. It can (1) decrease government spending, (2) raise

FIGURE 33.2 Contractionary fiscal policy.

Contractionary fiscal policy uses decreases in government spending, increases in taxes, or both, to reduce demand-pull inflation. Here, an increase in aggregate demand from AD_3 to AD_4 has driven the economy to point b and ratcheted the price level up to P_2 , where it becomes inflexible downward. If the economy's MPC is 0.75 and the multiplier therefore is 4, the government can either reduce its spending by \$3 billion or increase its taxes by \$4 billion (which will decrease consumption by \$3 billion) to eliminate the inflationary GDP gap of \$12 billion (= \$522 billion – \$510 billion). Aggregate demand will shift leftward, first from AD_4 to the dashed downsloping curve to its left, and then to AD_5 . With the price level remaining at P_2 , the economy will move from point b to point c and the inflationary GDP gap will disappear.

taxes, or (3) use some combination of those two policies. When the economy faces demand-pull inflation, fiscal policy should move toward a government **budget surplus**—tax revenues in excess of government spending.

But before discussing how the government can either decrease government spending or increase taxes to move toward a government budget surplus and control inflation, we have to keep in mind that the price level is like a ratchet. While increases in aggregate demand that expand real output beyond the full-employment level tend to ratchet the price level upward, declines in aggregate demand do not seem to push the price level downward. This means that stopping inflation is a matter of halting the rise of the price level, not trying to lower it to the previous level. It also means that the government must take the ratchet effect into account when deciding how big a cut in spending or an increase in taxes it should undertake.

Decreased Government Spending To control demand-pull inflation, the government can decrease aggregate demand by reducing government spending. To see why the ratchet effect matters so much, look at Figure 33.2 and consider what would happen if the government ignored the ratchet effect and attempted to design a spending-reduction policy to eliminate the inflationary GDP gap. Since the \$12 billion gap was caused by the \$20 billion rightward movement of the aggregate demand curve from AD_3 to AD_4 , the government might naively think that it could solve the problem by causing a \$20 billion leftward shift of the aggregate demand curve to move it back to where it originally was. It could attempt to do so by reducing government spending by \$5 billion and then allowing the multiplier effect to expand that initial decrease into a \$20 billion decline in aggregate demand. That would shift the aggregate demand curve leftward by \$20 billion, putting it back at AD_3 .

This policy would work fine if there were no ratchet effect and if prices were flexible. The economy's equilibrium would move back from point b to point a , with equilibrium GDP returning to the full-employment level of \$510 billion and the price level falling from P_2 back to P_1 .

But because there *is* a ratchet effect, this scenario is not what will actually happen. Instead, the ratchet effect implies that the price level is stuck at P_2 , so that the broken horizontal line at price level P_2 becomes important to the analysis. The fixed price level means that when the government reduces spending by \$5 billion to shift the aggregate demand curve back to AD_3 , it will actually cause a recession! The new equilibrium will not be at point a . It will be at point d , where aggregate demand curve AD_3 crosses the broken horizontal line. At point d , real GDP is only \$502 billion, \$8 billion below the full-employment level of \$510 billion.

The problem is that, with the price level downwardly inflexible at P_2 , the \$20 billion leftward shift of the aggregate

demand curve causes a full \$20 billion decline in real GDP. None of the change in aggregate demand can be dissipated as a decline in the price level. As a result, equilibrium GDP declines by the full \$20 billion, falling from \$522 billion to \$502 billion and putting it \$8 billion below potential output. By not taking the ratchet effect into account, the government has overdone the decrease in government spending, replacing a \$12 billion inflationary GDP gap with an \$8 billion recessionary GDP gap. This is clearly not what it had in mind.

Here's how it can avoid this scenario. First, the government takes account of the size of the inflationary GDP gap. It is \$12 billion. Second, it knows that with the price level fixed, the multiplier will be in full effect. Thus, it knows that any decline in government spending will be multiplied by a factor of 4. It then reasons that government spending will have to decline by only \$3 billion rather than \$5 billion. Why? Because the \$3 billion initial decline in government spending will be multiplied by 4, creating a \$12 billion decline in aggregate demand. Under the circumstances, a \$3 billion decline in government spending is the correct amount to exactly offset the \$12 billion GDP gap. This inflationary GDP gap is the problem that government wants to eliminate. To succeed, it need not undo the full increase in aggregate demand that caused the inflation in the first place.

Graphically, the horizontal distance between AD_4 and the dashed downsloping line to its left represents the \$3 billion decrease in government spending. Once the multiplier process is complete, this spending cut will shift the aggregate demand curve leftward from AD_4 to AD_5 . With the price level fixed at P_2 , the economy will come to equilibrium at point c . The economy will operate at its potential output of \$510 billion, and the inflationary GDP gap will be eliminated. Furthermore, because the government took the ratchet effect correctly into account, the government will not accidentally push the economy into a recession by making an overly large initial decrease in government spending.

Increased Taxes Just as government can use tax cuts to increase consumption spending, it can use tax *increases* to *reduce* consumption spending. If the economy in Figure 33.2 has an MPC of 0.75, the government must raise taxes by \$4 billion to achieve its fiscal policy objective. The \$4 billion tax increase reduces saving by \$1 billion (= the MPS of 0.25 \times \$4 billion). This \$1 billion reduction in saving, by definition, is not a reduction in spending. But the \$4 billion tax increase also reduces consumption spending by \$3 billion (= the MPC of 0.75 \times \$4 billion), as shown by the distance between AD_4 and the dashed downsloping line to its left in Figure 33.2. After the multiplier process is complete, this initial \$3 billion decline in consumption will cause aggregate demand to shift leftward by \$12 billion at each price level (multiplier of 4 \times \$3 billion). With the economy moving to point c , the inflationary GDP gap will be closed and the inflation will be halted.

Combined Government Spending Decreases and Tax Increases The government may choose to combine spending decreases and tax increases in order to reduce aggregate demand and check inflation. To check your understanding, determine why a \$1.5 billion decline in government spending combined with a \$2 billion increase in taxes would shift the aggregate demand curve from AD_4 to AD_5 . Also, if you were assigned Chapter 31, explain the three fiscal policy options for fighting inflation by referring to the inflationary-expenditure-gap concept developed with the aggregate expenditures model (Figure 31.7). And recall from the appendix to Chapter 32 that leftward shifts of the aggregate demand curve are associated with downshifts of the aggregate expenditures schedule.

Policy Options: G or T ?

Which is preferable as a means of eliminating recession and inflation? The use of government spending or the use of taxes? The answer depends largely on one's view as to whether the government is too large or too small.

Economists who believe there are many unmet social and infrastructure needs usually recommend that government spending be increased during recessions. In times of demand-pull inflation, they usually recommend tax increases. Both actions either expand or preserve the size of government.

Economists who think that the government is too large and inefficient usually advocate tax cuts during recessions and cuts in government spending during times of demand-pull inflation. Both actions either restrain the growth of government or reduce its size.

The point is that discretionary fiscal policy designed to stabilize the economy can be associated with either an expanding government or a contracting government.

QUICK REVIEW 33.1

- ✓ Discretionary fiscal policy is the purposeful change of government expenditures and tax collections by government to promote full employment, price stability, and economic growth.
- ✓ Expansionary fiscal policy consists of increases in government spending, reductions in taxes, or both, and is designed to expand real GDP by increasing aggregate demand.
- ✓ Contractionary fiscal policy entails decreases in government spending, increases in taxes, or both, and is designed to reduce aggregate demand and slow or halt demand-pull inflation.
- ✓ To be implemented correctly, contractionary fiscal policy must properly account for the ratchet effect and the fact that the price level will not fall as the government shifts the aggregate demand curve leftward.

Built-In Stability

L033.2 Explain the role of built-in stabilizers in moderating business cycles.

To some degree, government tax revenues change automatically over the course of the business cycle and in ways that stabilize the economy. This automatic response, or built-in stability, constitutes nondiscretionary (or “passive” or “automatic”) budgetary policy and results from the makeup of most tax systems. We did not include this built-in stability in our discussion of fiscal policy over the last few pages because we implicitly assumed that the same amount of tax revenue was being collected at each level of GDP. But the actual U.S. tax system is such that *net tax revenues* vary directly with GDP. (Net taxes are tax revenues less transfers and subsidies. From here on, we will use the simpler “taxes” to mean “net taxes.”)

Virtually any tax will yield more tax revenue as GDP rises. In particular, personal income taxes have progressive rates and thus generate more-than-proportionate increases in tax revenues as GDP expands. Furthermore, as GDP rises and more goods and services are purchased, revenues from corporate income taxes and from sales taxes and excise taxes also increase. And, similarly, revenues from payroll taxes rise as economic expansion creates more jobs. Conversely, when GDP declines, tax receipts from all these sources also decline.

Transfer payments (or “negative taxes”) behave in the opposite way from tax revenues. Unemployment compensation payments and welfare payments decrease during economic expansion and increase during economic contraction.

Automatic or Built-In Stabilizers

A **built-in stabilizer** is anything that increases the government's budget deficit (or reduces its budget surplus) during a recession and increases its budget surplus (or reduces its budget deficit) during an expansion without requiring explicit action by policymakers. As Figure 33.3 reveals, this is precisely what the U.S. tax system does. Government expenditures G are fixed and assumed to be independent of the level of GDP. Congress decides on a particular level of spending, but it does not determine the magnitude of tax revenues. Instead, it establishes tax rates, and the tax revenues then vary directly with the level of GDP that the economy achieves. Line T represents that direct relationship between tax revenues and GDP.

Economic Importance The economic importance of the direct relationship between tax receipts and GDP becomes apparent when we consider that:

- Taxes reduce spending and aggregate demand.
- Reductions in spending are desirable when the economy is moving toward inflation, whereas increases in spending are desirable when the economy is slumping.

FIGURE 33.3 Built-in stability. Tax revenues, T , vary directly with GDP, and government spending, G , is assumed to be independent of GDP. As GDP falls in a recession, deficits occur automatically and help alleviate the recession. As GDP rises during expansion, surpluses occur automatically and help offset possible inflation.

As shown in Figure 33.3, tax revenues automatically increase as GDP rises during prosperity, and since taxes reduce household and business spending, they restrain the economic expansion. That is, as the economy moves toward a higher GDP, tax revenues automatically rise and move the budget from deficit toward surplus. In Figure 33.3, observe that the high and perhaps inflationary income level GDP_3 automatically generates a contractionary budget surplus.

Conversely, as GDP falls during recession, tax revenues automatically decline, increasing spending by households and businesses and thus cushioning the economic contraction. With a falling GDP, tax receipts decline and move the government's budget from surplus toward deficit. In Figure 33.3, the low level of income GDP_1 will automatically yield an expansionary budget deficit.

Tax Progressivity Figure 33.3 reveals that the size of the automatic budget deficits or surpluses—and therefore built-in stability—depends on the responsiveness of tax revenues to changes in GDP. If tax revenues change sharply as GDP changes, the slope of line T in the figure will be steep and the vertical distances between T and G (the deficits or surpluses) will be large. If tax revenues change very little when GDP changes, the slope will be gentle and built-in stability will be low.

The steepness of T in Figure 33.3 depends on the tax system itself. In a **progressive tax system**, the average tax rate (= tax revenue/GDP) rises with GDP. In a **proportional tax system**, the average tax rate remains constant as GDP rises. In a **regressive tax system**, the average tax rate falls as GDP rises. The progressive tax system has the steepest tax line T of

the three. However, tax revenues will rise with GDP under both the progressive and the proportional tax systems, and they may rise, fall, or stay the same under a regressive tax system. The main point is this: The more progressive the tax system, the greater the economy's built-in stability.

The built-in stability provided by the U.S. tax system has reduced the severity of business fluctuations, perhaps by as much as 8 to 10 percent of the change in GDP that otherwise would have occurred.¹ In recession-year 2009, for example, revenues from the individual income tax fell by a staggering 22 percent. This decline helped keep household spending and real GDP from falling even more than they did. But built-in stabilizers can only dampen, not counteract, swings in real GDP. Discretionary fiscal policy (changes in tax rates and expenditures) or monetary policy (central bank-caused changes in interest rates) therefore may be needed to try to counter a recession or inflation of any appreciable magnitude.

Evaluating How Expansionary or Contractionary Fiscal Policy Is Determined

L033.3 Describe how the cyclically adjusted budget reveals the status of U.S. fiscal policy.

How can we determine whether a government's discretionary fiscal policy is expansionary, neutral, or contractionary? We cannot simply examine the actual budget deficits or surpluses that take place under the current policy because they will necessarily include the automatic changes in tax revenues that accompany every change in GDP. In addition, the expansionary or contractionary strength of any change in discretionary fiscal policy depends not on its absolute size but on how large it is relative to the size of the economy. So, in evaluating the status of fiscal policy, we must adjust deficits and surpluses to eliminate automatic changes in tax revenues and also compare the sizes of the adjusted budget deficits and surpluses to the level of potential GDP.

Cyclically Adjusted Budget

Economists use the **cyclically adjusted budget** (also called the *full-employment budget*) to adjust actual federal budget deficits and surpluses to account for the changes in tax revenues that happen automatically whenever GDP changes. The cyclically adjusted budget measures what the federal budget deficit or surplus would have been under existing tax rates and government spending levels if the economy had achieved its full-employment level of GDP (its potential output). The idea

¹Alan J. Auerbach and Daniel Feenberg, "The Significance of Federal Taxes as Automatic Stabilizers," *Journal of Economic Perspectives*, Summer 2000, p. 54.

essentially is to compare *actual* government expenditures with the tax revenues *that would have occurred* if the economy had achieved full-employment GDP. That procedure removes budget deficits or surpluses that arise simply because of cyclical changes in GDP and thus tell us nothing about whether the government's current discretionary fiscal policy is fundamentally expansionary, contractionary, or neutral.

Consider Figure 33.4a, where line G represents government expenditures and line T represents tax revenues. In full-employment year 1, government expenditures of \$500 billion equal tax revenues of \$500 billion, as indicated by the intersection of lines G and T at point a . The cyclically adjusted budget deficit in year 1 is zero—government expenditures equal the tax revenues forthcoming at the full-employment output GDP_1 . Obviously, the cyclically adjusted deficit *as a percentage of potential GDP* is also zero. The government's fiscal policy is neutral.

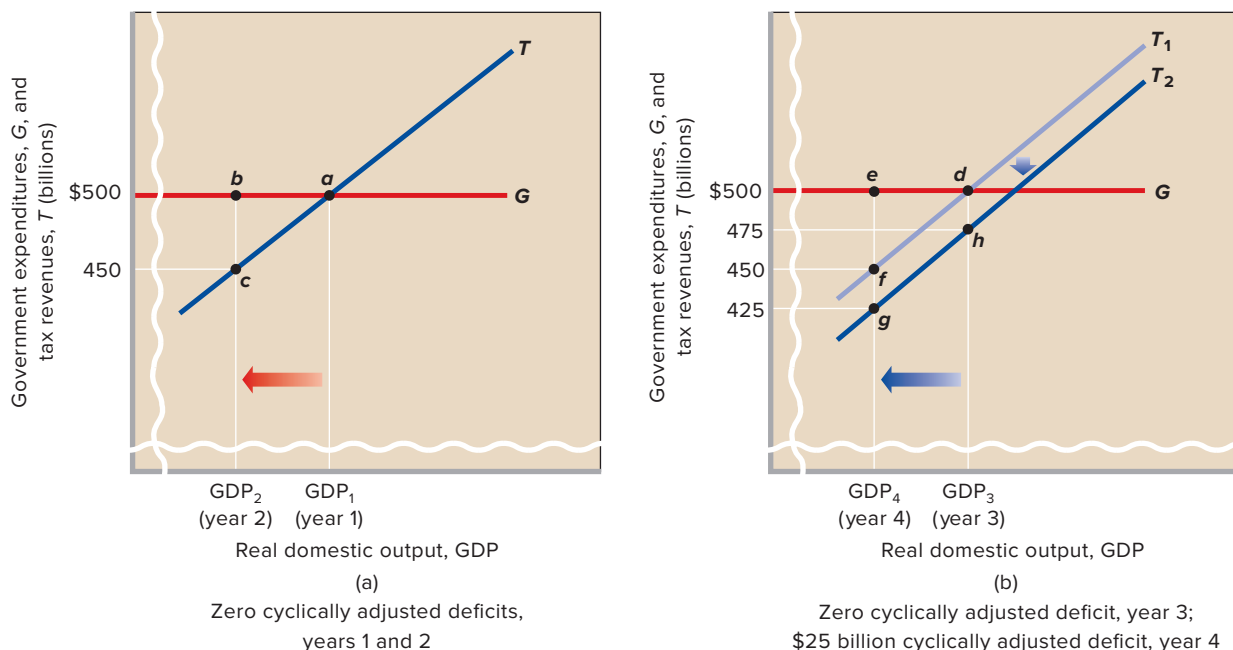

Now suppose that a recession occurs and GDP falls from GDP_1 to GDP_2 , as shown in Figure 33.4a. Let's also assume that the government takes no discretionary action, so lines G and T remain as shown in the figure. Tax revenues automatically fall to \$450 billion (point c) at GDP_2 , while government spending remains unaltered at \$500 billion (point b). A \$50 billion budget deficit (represented by distance bc) arises. But this **cyclical deficit** is simply a by-product of the economy's

slide into recession, not the result of discretionary fiscal actions by the government. We would be wrong to conclude from this deficit that the government is engaging in an expansionary fiscal policy. The government's fiscal policy has not changed. It is still neutral.

That fact is highlighted when we remove the cyclical part of the deficit and thus consider the cyclically adjusted budget deficit for year 2 in Figure 33.4a. The \$500 billion of government expenditures in year 2 is shown by b on line G . And, as shown by a on line T , \$500 billion of tax revenues would have occurred if the economy had achieved its full-employment GDP. Because both b and a represent \$500 billion, the cyclically adjusted budget deficit in year 2 is zero, as is this deficit as a percentage of potential GDP. Since the cyclically adjusted deficits are zero in both years, we know that government did not change its discretionary fiscal policy, even though a recession occurred and an actual deficit of \$50 billion resulted.

Next, consider Figure 33.4b. Suppose that real output declined from full-employment GDP_3 in year 3 to GDP_4 in year 4. Also suppose that government responded to the recession by reducing tax rates in year 4, as represented by the downward shift of the tax line from T_1 to T_2 . What has happened to the size of the cyclically adjusted deficit? Government expenditures in year 4 are \$500 billion, as shown by e . Compare that amount with the \$475 billion of tax revenues that would occur

FIGURE 33.4 Cyclically adjusted deficits. (a) In the left-hand graph, the cyclically adjusted deficit is zero at the full-employment output GDP_1 . But it is also zero at the recessionary output GDP_2 because the \$500 billion of government expenditures at GDP_2 equals the \$500 billion of tax revenues that would be forthcoming at the full-employment GDP_1 . There has been no change in fiscal policy. (b) In the right-hand graph, discretionary fiscal policy, as reflected in the downward shift of the tax line from T_1 to T_2 , has increased the cyclically adjusted budget deficit from zero in year 3 (before the tax cut) to \$25 billion in year 4 (after the tax cut). This is found by comparing the \$500 billion of government spending in year 4 with the \$475 billion of taxes that would accrue at the full-employment GDP_3 . Such a rise in the cyclically adjusted deficit (as a percentage of potential GDP) identifies an expansionary fiscal policy.

if the economy achieved its full-employment GDP. That is, compare position e on line G with position h on line T_2 . The \$25 billion of tax revenues by which e exceeds h is the cyclically adjusted budget deficit for year 4. As a percentage of potential GDP, the cyclically adjusted budget deficit has increased from zero in year 3 (before the tax-rate cut) to some positive percent [= $(\$25 \text{ billion}/\text{GDP}_3) \times 100$] in year 4. This increase in the relative size of the full-employment deficit between the two years reveals that the new fiscal policy is *expansionary*.

In contrast, if we observed a cyclically adjusted deficit (as a percentage of potential GDP) of zero in one year, followed by a cyclically adjusted budget surplus in the next, we could conclude that fiscal policy has changed from being neutral to being contractionary. Because the cyclically adjusted budget adjusts for automatic changes in tax revenues, the increase in the cyclically adjusted budget surplus reveals that government either decreased its spending (G) or increased tax rates such that tax revenues (T) increased. These changes in G and T are precisely the discretionary actions that we have identified as elements of a *contractionary* fiscal policy.

Recent and Projected U.S. Fiscal Policy

LO33.4 Summarize recent U.S. fiscal policy and the projections for U.S. fiscal policy over the next few years.

Table 33.1 lists the actual federal budget deficits and surpluses (column 2) and the cyclically adjusted deficits and surpluses (column 3), as percentages of actual GDP and potential GDP, respectively, between 2000 and 2015. Observe that the cyclically adjusted deficits are generally smaller than the actual deficits. This is because the actual deficits include cyclical deficits, whereas the cyclically adjusted deficits eliminate them. Only cyclically adjusted surpluses and deficits as percentages of potential GDP (column 3) provide the information needed to assess discretionary fiscal policy and determine whether it is expansionary, contractionary, or neutral.

Fiscal Policy from 2000 to 2007

Take a look at the data for 2000, for example, which shows that fiscal policy was contractionary that year. Note that the actual budget surplus was 2.4 percent of GDP in 2000 and the cyclically adjusted budget surplus was 1.2 percent of potential GDP. Because the economy was fully employed and corporate profits were strong, tax revenues poured into the federal government and exceeded government expenditures.

But not all was well in 2000. Specifically, the so-called dot-com stock market bubble burst that year, and the U.S. economy noticeably slowed over the latter half of the year. In March 2001, the economy slid into a recession. Congress

and the Bush administration responded by cutting taxes by \$44 billion in 2001 and scheduling an additional \$52 billion of cuts for 2002. These stimulus policies helped boost the economy and offset the recession as well as cushion the economic blow delivered by the September 11, 2001, terrorist attacks. In March 2002, Congress passed further tax cuts totaling \$122 billion over two years and extended unemployment benefits.

As Table 33.1 reveals, the cyclically adjusted budget moved from a surplus of 1.2 percent of potential GDP in 2000 to a deficit of –1.2 percent two years later in 2002. Fiscal policy had definitely turned expansionary. Nevertheless, the economy remained sluggish through 2002 and into 2003. In June 2003 Congress again cut taxes, this time by a much larger \$350 billion over several years. Specifically, the tax legislation accelerated the reduction of marginal tax rates already scheduled for future years and slashed tax rates on income from dividends and capital gains. It also increased tax breaks for families and small businesses. Note from the table that this tax package increased the cyclically adjusted budget deficit as a percentage of potential GDP to –2.7 percent in 2003. The economy strengthened and both real output and employment grew between 2003 and 2007. By 2007 full employment had been restored, although a –1.3 percent cyclically adjusted budget deficit still remained.

Fiscal Policy during and after the Great Recession

As pointed out in previous chapters, major economic trouble began in 2007. In the summer of 2007, a crisis in the market for mortgage loans flared up. Later in 2007, that crisis spread rapidly to other financial markets, threatened the survival of several major U.S. financial institutions, and severely disrupted the entire financial system. As credit markets began to freeze, general pessimism spread beyond the financial markets to the overall economy. Businesses and households retrenched on their borrowing and spending, and in December 2007, the economy entered a recession. Over the following two years, it became known as the Great Recession—one of the steepest and longest economic downturns since the 1930s.

In 2008 Congress acted rapidly to pass an economic stimulus package. This law provided a total of \$152 billion in stimulus, with some of it coming as tax breaks for businesses, but most of it delivered as checks of up to \$600 each to taxpayers, veterans, and Social Security recipients.

As a percentage of GDP, the *actual* federal budget deficit jumped from -1.2 percent in 2007 to -3.2 percent in 2008. This increase resulted from an automatic drop-off of tax revenues during the recession, along with the tax rebates (fiscal stimulus checks) paid out in 2008. As shown in Table 33.1, the *cyclically adjusted* budget deficit rose from -1.3 percent of potential GDP in 2007 to -2.9 percent in 2008. This increase in the cyclically adjusted budget reveals that fiscal policy in 2008 was expansionary.

The government hoped that those receiving checks would spend the money and thus boost consumption and aggregate demand. But households instead saved substantial parts of the money from the checks or used some of the money to pay down credit card loans. Although this stimulus plan boosted output somewhat in mid-2008, it was neither as expansionary nor as long-lasting as policymakers had hoped. The continuing forces of the Great Recession simply overwhelmed the policy.

With the economy continuing its precipitous slide, the Obama administration and Congress enacted the American Recovery and Reinvestment Act of 2009. This gigantic \$787 billion program—coming on top of a \$700 billion rescue package for financial institutions—consisted of low- and middle-income tax rebates, plus large increases in expenditures on infrastructure, education, and health care. The idea was to flood the economy with additional spending to try to boost aggregate demand and get people back to work.

The tax cuts in the package were aimed at lower- and middle-income individuals and households, who were thought to be more likely than high-income people to spend (rather than save) the extra income from the tax rebates. Rather than sending out lump-sum stimulus checks as in 2008, the new tax rebates showed up as small increases in workers' monthly payroll checks. With smaller amounts per month rather than a

GLOBAL PERSPECTIVE 33.1

Cyclically Adjusted Budget Deficits or Surpluses as a Percentage of Potential GDP, Selected Nations

In 2014, five years after the end of the global recession, about half of the countries in the developed world had cyclically adjusted budget deficits that reflected some degree of expansionary fiscal policy.

single large check, the government hoped that people would spend the bulk of their enhanced income—rather than save it as they had done with the one-time-only, lump-sum checks received in 2008. The second part of the fiscal policy (60 percent of the funding) consisted of increases in government expenditures on a wide assortment of programs, including transportation, education, and aid to state governments. The highly stimulative fiscal policy for 2009 is fully reflected in column 3 of Table 33.1. The cyclically adjusted budget deficit rose dramatically from -2.9 percent of potential GDP in 2008 to a very high -7.1 percent of potential GDP in 2009.

The recession officially ended during the summer of 2009, but the economy did not rebound vigorously. Unemployment remained elevated and tax collections were low due to a stagnant economy. As a result, policymakers decided to continue with large amounts of fiscal stimulus. Annual actual (not cyclically adjusted) budget deficits amounted to -4.1 , -2.8 , and -2.4 percent of GDP, respectively, in years 2013, 2014, and 2015. The cyclically adjusted budget deficits for those years were, respectively, -2.6 , -1.6 , and -1.6 percent of potential GDP. Thus, while the intensity of fiscal stimulus was gradually diminishing, it remained substantially stimulatory. The

The budget surpluses of 1998 through 2001 were the first budget surpluses since 1969. Deficits reemerged after the 2001 recession and then ballooned massively with the Great Recession of 2007–2009. Deficits are projected to remain high for many years to come, though not nearly as high as in the years immediately following the Great Recession.

recession had been exceptionally strong; so was the ongoing fiscal response.

Other nations also experienced recessions and also responded with expansionary fiscal policies. Global Perspective 33.1 shows the magnitudes of the cyclically adjusted surpluses and deficits of a number of countries in 2014.

Past and Projected Budget Deficits and Surpluses

Figure 33.5 shows the absolute magnitudes of actual (not cyclically adjusted) U.S. budget surpluses and deficits, from 1997 through 2015. It also shows the projected future deficits through 2021, as estimated by the Congressional Budget Office (CBO). In recession year 2009, the federal budget deficit reached \$1,413 billion, mainly but not totally due to reduced tax revenues from lower income and record amounts of stimulus spending. The CBO projects high deficits for several years to come. But projected deficits and surpluses are subject to large and frequent changes, as government alters its fiscal policy and GDP growth accelerates or slows. So we suggest that you update this figure by going to the Congressional Budget Office website, www.cbo.gov, and finding the document titled *The Budget and Economic Outlook*. Near the start of that document, you should find Summary Table 1. The numbers are in the row labeled “Deficit (–) or Surplus.”

Problems, Criticisms, and Complications of Implementing Fiscal Policy

L033.5 Discuss the problems that governments may encounter in enacting and applying fiscal policy.

Economists recognize that governments may encounter a number of significant problems in enacting and applying fiscal policy.

Problems of Timing

Several problems of timing may arise in connection with fiscal policy:

- **Recognition lag** The recognition lag is the time between the beginning of recession or inflation and the certain awareness that it is actually happening. This lag arises because the economy does not move smoothly through the business cycle. Even during good times, the economy has slow months interspersed with months of rapid growth and expansion. This makes recognizing a recession difficult since several slow months will have to happen in succession before people can conclude with any confidence that the good times are over and a recession has begun.

The same is true with inflation. Even periods of moderate inflation have months of high inflation—so that several high-inflation months must come in sequence before people can confidently conclude that inflation has moved to a higher level.

Attempts to reduce the length of the recognition lag by trying to predict the future course of the economy also have proven to be highly difficult, at best. As a result, the economy is often 4 to 6 months into a recession or inflation before the situation is clearly discernible in the relevant statistics. Due to this recognition lag, the economic downside or the inflation may become more serious than it would have if the situation had been identified and acted on sooner.

- **Administrative lag** The wheels of democratic government turn slowly. There will typically be a significant lag between the time the need for fiscal action is recognized and the time action is taken. Following the terrorist attacks of September 11, 2001, the U.S. Congress was stalemated for 5 months before passing a compromise economic stimulus law in March 2002. (In contrast, the Federal Reserve began lowering interest rates the week after the attacks.)
- **Operational lag** A lag also occurs between the time fiscal action is taken and the time that action affects output, employment, or the price level. Although changes in tax rates can be put into effect relatively quickly once new laws are passed, government spending on public works—new dams, interstate highways, and so on—requires long planning periods and even longer periods of construction. Such spending is of questionable use in offsetting short (for example, 6- to 12-month) periods of recession. Consequently, discretionary fiscal policy has increasingly relied on tax changes rather than on changes in spending as its main tool.

Political Considerations

Fiscal policy is conducted in a political arena. That reality not only may slow the enactment of fiscal policy but also may create the potential for political considerations swamping economic considerations in its formulation. It is a human trait to rationalize actions and policies that are in one's self-interest. Politicians are very human—they want to get reelected. A strong economy at election time will certainly help them. So they may favor large tax cuts under the guise of expansionary fiscal policy even though that policy is economically inappropriate. Similarly, they may rationalize increased government spending on popular items such as farm subsidies, health care, highways, education, and homeland security.

At the extreme, elected officials and political parties might collectively “hijack” fiscal policy for political purposes, cause inappropriate changes in aggregate demand, and

thereby cause (rather than avert) economic fluctuations. For instance, before an election, they may try to stimulate the economy to improve their reelection hopes. And then after the election, they may try to use contractionary fiscal policy to dampen the excessive aggregate demand that they caused with their preelection stimulus. In short, elected officials may cause so-called **political business cycles**—swings in overall economic activity and real GDP resulting from election-motivated fiscal policy, rather than from inherent instability in the private sector. Political business cycles are difficult to document and prove, but there is little doubt that political considerations weigh heavily in the formulation of fiscal policy. The question is how often those political considerations run counter to “sound economics.”

Future Policy Reversals

Fiscal policy may fail to achieve its intended objectives if households expect future reversals of policy. Consider a tax cut, for example. If taxpayers believe the tax reduction is temporary, they may save a large portion of their tax cut, reasoning that rates will return to their previous level in the future. They save more now so that they will be able to draw on this extra savings to maintain their future consumption levels if taxes do indeed rise again in the future. So a tax reduction thought to be temporary may not increase present consumption spending and aggregate demand by as much as our simple model (Figure 33.1) suggests.

The opposite may be true for a tax increase. If taxpayers think it is temporary, they may reduce their saving to pay the tax while maintaining their present consumption. They may reason they can restore their saving when the tax rate again falls. So the tax increase may not reduce current consumption and aggregate demand by as much as policymakers intended.

To the extent that this so-called *consumption smoothing* occurs over time, fiscal policy will lose some of its strength. The lesson is that tax-rate changes that households view as permanent are more likely to alter consumption and aggregate demand than tax changes they view as temporary.

Offsetting State and Local Finance

The fiscal policies of state and local governments are frequently *pro-cyclical*, meaning that they worsen rather than correct recession or inflation. Unlike the federal government, most state and local governments face constitutional or other legal requirements to balance their budgets. Like households and private businesses, state and local governments increase their expenditures during prosperity and cut them during recession.

During the Great Depression of the 1930s, most of the increase in federal spending was offset by decreases in state and local spending. During and immediately following the recession of 2001, many state and local governments had to offset lower tax revenues resulting from the reduced personal

income and spending of their citizens. They offset the decline in revenues by raising tax rates, imposing new taxes, and reducing spending.

In view of these past experiences, the \$787 billion fiscal package of 2009 made a special effort to reduce this problem by giving substantial aid dollars to state governments. Because of the sizable federal aid, the states did not have to increase taxes and reduce expenditure by as much as otherwise. So their collective fiscal actions did not fight as much against the increase in aggregate demand that the federal government wanted to achieve with its tax cuts and expenditure increases.

Crowding-Out Effect

Another potential flaw of fiscal policy is the so-called **crowding-out effect**: An expansionary fiscal policy (deficit spending) may increase the interest rate and reduce investment spending, thereby weakening or canceling the stimulus of the expansionary policy. The rising interest rate might also potentially crowd out interest-sensitive consumption spending (such as purchasing automobiles on credit). But since investment is the most volatile component of GDP, the crowding-out effect focuses its attention on investment and whether the stimulus provided by deficit spending may be partly or even fully neutralized by an offsetting reduction in investment spending.

To see the potential problem, realize that whenever the government borrows money (as it must if it is deficit spending), it increases the overall demand for money. If the monetary authorities are holding the money supply constant, this increase in demand will raise the price paid for borrowing money: the interest rate. Because investment spending varies inversely with the interest rate, some investment will be choked off or “crowded out.”

Economists vary in their opinions about the strength of the crowding-out effect. An important thing to keep in mind is that crowding out is likely to be less of a problem when the economy is in recession because investment demand tends to be weak. Why? Because output purchases slow during recessions and therefore most businesses end up with substantial excess capacity. As a result, they do not have much incentive to add new machinery or build new factories. After all, why should they add capacity when some of the capacity they already have is lying idle?

With investment demand weak during a recession, the crowding-out effect is likely to be very small. Simply put, there is not much investment for the government to crowd out. Even if deficit spending does increase the interest rate, the effect on investment may be fully offset by the improved investment prospects that businesses expect from the fiscal stimulus.

By contrast, when the economy is operating at or near full capacity, investment demand is likely to be quite strong so

that crowding out will probably be a much more serious problem. When the economy is booming, factories will be running at or near full capacity and firms will have high investment demand for two reasons. First, equipment running at full capacity wears out fast, so firms will be investing substantial amounts just to replace machinery and equipment that wears out and depreciates. Second, the economy is likely to be growing overall so that firms will be heavily investing to *add* to their production capacity to take advantage of the greater anticipated demand for their outputs.

Current Thinking on Fiscal Policy

Where do these complications leave us as to the advisability and effectiveness of discretionary fiscal policy? In view of the complications and uncertain outcomes of fiscal policy, some economists argue that it is better not to engage in it at all. Those holding that viewpoint to the superiority of monetary policy (changes in interest rates engineered by the Federal Reserve) as a stabilizing device or believe that most economic fluctuations tend to be mild and self-correcting.

But most economists believe that fiscal policy remains an important, useful policy lever in the government’s macroeconomic toolkit. The current popular view is that fiscal policy can help push the economy in a particular direction but cannot fine-tune it to a precise macroeconomic outcome. Mainstream economists generally agree that monetary policy is the best month-to-month stabilization tool for the U.S. economy. If monetary policy is doing its job, the government should maintain a relatively neutral fiscal policy, with a cyclically adjusted budget deficit or surplus of no more than 2 percent of potential GDP. It should hold major discretionary fiscal policy in reserve to help counter situations where recession threatens to be deep and long lasting, as in 2008 and 2009, or where a substantial reduction in aggregate demand might help the Federal Reserve to quell a major bout of inflation.

Finally, economists agree that any proposed fiscal policy should be evaluated for its potential positive and negative impacts on long-run productivity growth. The short-run policy tools used for conducting active fiscal policy often have long-run impacts. Countercyclical fiscal policy should be shaped to strengthen, or at least not impede, the growth of long-run aggregate supply (which would be shown in Figure 32.5 as a rightward shift of the long-run aggregate supply curve). For example, a tax cut might be structured to enhance work effort, strengthen investment, and encourage innovation. Alternatively, an increase in government spending might center on preplanned projects for public capital (highways, mass transit, ports, airports), which are complementary to private investment and thus support long-term economic growth.

QUICK REVIEW 33.2

- ✓ Automatic changes in net taxes (taxes minus transfers) add a degree of built-in stability to the economy.
- ✓ Cyclical deficits arise from declines in net tax revenues that automatically occur as the economy recedes and incomes and profits fall.
- ✓ The cyclically adjusted budget eliminates cyclical effects on net tax revenues; it compares actual levels of government spending to the projected levels of net taxes that would occur if the economy were achieving its full-employment output.
- ✓ Time lags, political problems, expectations, and state and local finances complicate fiscal policy.
- ✓ The crowding-out effect indicates that an expansionary fiscal policy may increase the interest rate and reduce investment spending.

The U.S. Public Debt

L033.6 Discuss the size, composition, and consequences of the U.S. public debt.

The U.S. national debt, or **public debt**, is essentially the accumulation of all past federal deficits and surpluses. The deficits have greatly exceeded the surpluses and have emerged mainly from war financing, recessions, and fiscal policy. In 2015, the total public debt was \$18.2 trillion—\$10.7 trillion held by the public, excluding the Federal Reserve; and \$7.5 trillion held by federal agencies and the Federal Reserve. Between 2007 and 2009, the total public debt expanded by a huge \$2.9 trillion. During the Great Recession, federal tax revenues plummeted because incomes and profit fell, and federal expenditures jumped because of huge spending to rescue failing financial institutions and to stimulate the shrinking economy.

Because large annual deficits continued over the next several years, the total public debt grew past \$18.2 trillion in late 2015. The debt had more than doubled in just over nine years, growing from \$8.5 trillion in late 2006 to \$18.2 trillion in late 2015. You can find the current size of the public debt at the website of the Department of Treasury, Bureau of the Fiscal Service, or at <http://treasurydirect.gov/NP/debt/current>. At this site, you will see that the U.S. Treasury defines “the public” to include the Federal Reserve. But because the Federal Reserve is the nation’s central bank, economists view it as essentially part of the federal government and not part of the public. Economists typically focus on the part of the debt that is not owned by the federal government and the Federal Reserve.

Ownership

The total public debt of \$18.2 trillion represents the total amount of money owed by the federal government to the

holders of **U.S. government securities**: financial instruments issued by the federal government to borrow money to finance expenditures that exceed tax revenues. U.S. government securities (loan instruments) are of four types: *Treasury bills* (short-term securities), *Treasury notes* (medium-term securities), *Treasury bonds* (long-term securities), and *U.S. savings bonds* (long-term, nonmarketable bonds).

Figure 33.6 shows that the public, sans the Federal Reserve, held 59 percent of the federal debt in 2015 and that federal government agencies and the Federal Reserve held the remaining 41 percent. The federal agencies hold U.S. government securities as risk-free assets that they can cash in as needed to make future payments. The Federal Reserve holds these securities to facilitate the “open-market operations” that it uses to control the nation’s money supply (Chapter 36). Observe that “the public” in the pie chart consists of individuals here and abroad, state and local governments, and U.S. financial institutions. Foreigners held about 34 percent of the total U.S. public debt in 2015, meaning that most of the U.S. public debt is held internally and not externally. Americans owed 66 percent of the public debt to Americans. Of the \$6.1 trillion

The \$18.2 trillion public debt can be divided into the 59 percent held by the public (excluding the Federal Reserve), and the proportion held by federal agencies and the Federal Reserve System (41 percent). Of the total debt, 34 percent is foreign-owned.

of debt held by foreigners, China held 20 percent, Japan held 18 percent, and oil-exporting nations held 5 percent.

Debt and GDP

A simple statement of the absolute size of the debt ignores the fact that the wealth and productive ability of the U.S. economy is also vast. A wealthy, highly productive nation can incur and carry a large public debt much more easily than a poor nation can. A more meaningful measure of the public debt relates it to an economy's GDP. Figure 33.7 shows the yearly relative sizes of the U.S. public debt held outside the Federal Reserve and federal agencies. In 2015 the percentage was 75 percent. Most noticeably, the percentage rose dramatically starting in 2008 because of massive annual budget deficits.

International Comparisons

It is not uncommon for countries to have sizable public debts. As shown in Global Perspective 33.2, the public debt as a percentage of real GDP in the United States is neither particularly high nor low relative to such debt percentages in other advanced industrial nations.

Interest Charges

Many economists conclude that the primary burden of the debt is the annual interest charge accruing on the bonds sold to finance the debt. In 2015 interest on the total public debt was \$400 billion. Although this amount is sizable in absolute terms, it was only 2.2 percent of GDP for 2015. So, the federal government had to collect taxes equal to 2.2 percent of GDP to service the total public debt. This percentage was unchanged

from 2000 despite the much higher total public debt. That was possible because interest rates were being kept extremely low

by the Federal Reserve in order to help stimulate the economy in the wake of the Great Recession (Chapter 36).

False Concerns

You may wonder if the large public debt might bankrupt the United States or at least place a tremendous burden on your children and grandchildren. Fortunately, these are largely false concerns. People were wondering the same things 50 years ago!

Bankruptcy

The large U.S. public debt does not threaten to bankrupt the federal government, leaving it unable to meet its financial obligations. There are two main reasons: refinancing and taxation.

Refinancing As long as the U.S. public debt is viewed by lenders as manageable and sustainable, the public debt is easily refinanced. As portions of the debt come due on maturing Treasury bills, notes, and bonds each month, the government does not cut expenditures or raise taxes to provide the funds required. Rather, it refinances the debt by selling new bonds and using the proceeds to pay holders of the maturing bonds. The new bonds are in strong demand because lenders can obtain a market-determined interest return with no risk of default by the federal government.

Of course, refinancing could become an issue with a high enough debt-to-GDP ratio. Some countries such as Greece have run into this problem. High and rising ratios in the United States might raise fears that the U.S. government might be unable to pay back loans as they come due. But, with the present U.S. debt-to-GDP ratio and the prospects of long-term economic growth, this is a false concern for the United States.

Taxation The federal government has the constitutional authority to levy and collect taxes. A tax increase is a government option for gaining sufficient revenue to pay interest and principal on the public debt. Financially distressed private households and corporations cannot extract themselves from their financial difficulties by taxing the public. If their incomes or sales revenues fall short of their expenses, they can indeed go bankrupt. But the federal government does have the option to impose new taxes or increase existing tax rates if necessary to finance its debt. Such tax hikes may be politically unpopular and may weaken incentives to work and invest, but they *are* a means of raising funds to finance the debt.

Burdening Future Generations

In 2015 public debt per capita was \$56,368. Was each child born in 2015 handed a \$56,368 bill from the federal government? Not really. The public debt does not impose as much of a burden on future generations as commonly thought.

The United States owes a substantial portion of the public debt to itself. U.S. citizens and institutions (banks, businesses, insurance companies, governmental agencies, and

trust funds) own about 66 percent of the U.S. government securities. Although that part of the public debt is a liability to Americans (as taxpayers), it is simultaneously an asset to Americans (as holders of Treasury bills, Treasury notes, Treasury bonds, and U.S. savings bonds).

To eliminate the American-owned part of the public debt would require a gigantic transfer payment from Americans to Americans. Taxpayers would pay higher taxes, and holders of the debt would receive an equal amount for their U.S. government securities. Purchasing power in the United States would not change. Only the repayment of the 34 percent of the public debt owned by foreigners would negatively impact U.S. purchasing power.

The public debt increased sharply during the Second World War. But the decision to finance military purchases through the sale of government bonds did not shift the economic burden of the war to future generations. The economic cost of the Second World War consisted of the civilian goods society had to forgo in shifting scarce resources to war goods production (recall production possibilities analysis). Regardless of whether society financed this reallocation through higher taxes or through borrowing, the real economic burden of the war would have been the same. That burden was borne almost entirely by those who lived during the war. They were the ones who did without a multitude of consumer goods to enable the United States to arm itself and its allies.

The next generation inherited the debt from the war but also an equal amount of government bonds that would pay them cash in future years. It also inherited the enormous benefits from the victory—namely, preserved political and economic systems at home and the “export” of those systems to Germany, Italy, and Japan. Those outcomes enhanced post-war U.S. economic growth and helped raise the standard of living of future generations of Americans.

Substantive Issues

Although the preceding issues relating to the public debt are false concerns, a number of substantive issues are not. Economists, however, attach varying degrees of importance to them.

Income Distribution

The distribution of ownership of government securities is highly uneven. Some people own much more than the \$56,368-per-person portion of government securities; other people own less or none at all. In general, the ownership of the public debt is concentrated among wealthier groups, who own a large percentage of all stocks and bonds. Because the overall federal tax system is only slightly progressive, payment of interest on the public debt mildly increases income inequality. Income is transferred from people who, on average, have lower incomes to the higher-income bondholders. If greater income equality is one of society’s goals, then this redistribution is undesirable.

Incentives

The current public debt necessitates annual interest payments of \$400 billion. With no increase in the size of the debt, that interest charge must be paid out of tax revenues. Higher taxes may dampen incentives to bear risk, to innovate, to invest, and to work. So, in this indirect way, a large public debt may impair economic growth and therefore impose a burden of reduced output (and income) on future generations.

Foreign-Owned Public Debt

The 34 percent of the U.S. debt held by citizens and institutions of foreign countries *is* an economic burden to Americans. Because we do not owe that portion of the debt “to ourselves,” the payment of interest and principal on this **external public debt** enables foreigners to buy some of our output. In return for the benefits derived from the borrowed funds, the United States transfers goods and services to foreign lenders. Of course, Americans also own debt issued by foreign governments, so payment of principal and interest by those governments transfers some of their goods and services to Americans.

Crowding-Out Effect Revisited

A potentially more serious problem is the financing (and continual refinancing) of the large public debt, which can transfer a real economic burden to future generations by passing on to them a smaller stock of capital goods. This possibility involves the previously discussed crowding-out effect: the idea that public borrowing drives up real interest rates, which reduces private investment spending. If public borrowing only happened during recessions, crowding out would not likely be much of a problem. Because private investment demand tends to be weak during recessions, any increase in interest rates caused by public borrowing will at most cause a small reduction in investment spending.

In contrast, the need to continuously finance a large public debt may be more troublesome. At times, that financing requires borrowing large amounts of money when the economy is near or at its full-employment output. Because this usually is when private demand is strong, any increase in interest rates caused by the borrowing necessary to refinance the debt may result in a substantial decline in investment spending. If the amount of current investment crowded out is extensive, future generations will inherit an economy with a smaller production capacity and, other things equal, a lower standard of living.

A Graphical Look at Crowding Out We know from Chapter 30 that the amount of investment spending is inversely related to the real interest rate. When graphed, that relationship is shown as a downsloping investment demand curve, such as either ID_1 or ID_2 in Figure 33.8. Let’s first consider curve ID_1 . (Ignore curve ID_2 for now.) Suppose that government borrowing increases the real interest rate from 6 percent to 10 percent. Investment spending will then fall from \$25 billion to

\$15 billion, as shown by the economy’s move from *a* to *b*. That is, the financing of the debt will compete with the financing of private investment projects and crowd out \$10 billion of private investment. So the stock of private capital handed down to future generations will be \$10 billion less than it would have been without the need to finance the public debt.

Public Investments and Public-Private Complementarities But even with crowding out, two factors could partly or fully offset the net economic burden shifted to future generations. First, just as private expenditures may involve either consumption or investment, so it is with public goods. Part of the government spending enabled by the public debt is for public investment outlays (for example, highways, mass transit systems, and electric power facilities) and “human capital” (for example, investments in education, job training, and health). Like private expenditures on machinery and equipment, those **public investments** increase the economy’s future production capacity. Because of the financing through debt, the stock of public capital passed on to future generations may be higher than otherwise. That greater stock of public capital may offset the diminished stock of private capital resulting from the crowding-out effect, leaving overall production capacity unimpaired.

So-called public-private complementarities are a second factor that could reduce the crowding-out effect. Some

FIGURE 33.8 The investment demand curve and the crowding-out effect.

If the investment demand curve (ID_1) is fixed, the increase in the interest rate from 6 percent to 10 percent caused by financing a large public debt will move the economy from *a* to *b*, crowding out \$10 billion of private investment and decreasing the size of the capital stock inherited by future generations. However, if the public goods enabled by the debt improve the investment prospects of businesses, the private investment demand curve will shift rightward, as from ID_1 to ID_2 . That shift may offset the crowding-out effect wholly or in part. In this case, it moves the economy from *a* to *c*.

The Social Security and Medicare Shortfalls

Social Security and Medicare Face Gigantic Future Funding Shortfalls. Metaphorically Speaking, Some Economists See These Programs as Financial and Political Time Bombs.

The American population, on average, is getting decidedly older. The percentage of the population age 62 or older will rise substantially over the next several decades, with the greatest increases for people age 75 and above. In the future, more people will be receiving Social Security benefits (income during retirement) and Medicare (medical care during retirement) for longer periods. Each person's benefits will be paid for by fewer workers. The number of workers per Social Security and Medicare beneficiary was roughly 5:1 in 1960. Today it is 3:1, and by 2040 it will be only 2:1.

The combined cost of the Social Security and Medicare programs was 8.5 percent of GDP in 2014, and that percentage is projected to grow to 11.4 percent of GDP in 2035 and 12.2 percent of GDP in 2086.*

The Social Security Shortfall Social Security is the major public retirement program in the United States. The program costs \$888 billion annually and is financed by a 12.4 percent tax on earnings up to a set level of earnings (\$118,500 in 2016). Half the tax (6.2 percent) is paid by the worker; the other half by the employer. Social Security is largely an annual “pay-as-you-go” plan, meaning that most of the current revenues from the Social Security tax are paid to current Social Security retirees. Through the start of 2009, Social Security revenues exceeded Social Security payouts in anticipation of the large benefits promised to

*Social Security and Medicare Board of Trustees, “Status of the Social Security and Medicare Programs: A Summary of the 2015 Annual Reports,” www.ssa.gov. This publication is also the source of most of the statistical information that follows.

public and private investments are complementary. Thus, the public investment financed through debt could spur some private-sector investment by increasing its expected rate of return. For example, a federal building in a city may encourage private investment in the form of nearby office buildings, shops, and restaurants. Through its complementary effect, the spending on public capital may shift the private investment demand curve to the right, as from ID_1 to ID_2 in Figure 33.8. Even though the government borrowing boosts the interest rate from 6 percent to 10 percent, total private investment need not fall. In the case shown as the move from a to c in Figure 33.8, it remains at \$25 billion. Of course, the increase in investment demand might be smaller than that shown. If it were smaller, the crowding-out effect would not be fully offset. But the point is that an increase in investment demand may counter the decline in investment that would otherwise result from the higher interest rate.

the baby boomers when they retire. That excess inflow was used to buy U.S. Treasury securities that were credited to a government account called the Social Security Trust Fund. But the combined accumulation of money in the trust fund through 2009 plus the projected future revenues from the payroll tax in later years was expected to be greatly inadequate for paying the promised retirement benefits to all future retirees.

This underfunding of future retirement promises was brought into sharper focus in the latter half of 2009 when, for the first time, Social Security revenues fell below Social Security retirement payouts and the system started shifting money from the trust fund to make up the difference. The trust fund is expected to be exhausted in 2033. For each year thereafter, annual tax revenues will cover only 75 percent of the promised benefits.

- ✓ The U.S. public debt—\$18.2 trillion in 2015—is essentially the total accumulation of all past federal budget deficits and surpluses; about 34 percent of the U.S. public debt is held by foreigners.
- ✓ The U.S. public debt held by the public (excluding the Federal Reserve) was 75 percent of GDP in 2015, up from 33 percent in 2000.
- ✓ The federal government is in no danger of going bankrupt because it needs only to refinance (not retire) the public debt and it can raise revenues, if needed, through higher taxes.
- ✓ The borrowing and interest payments associated with the public debt may (a) increase income inequality; (b) require higher taxes, which may dampen incentives; and (c) impede the growth of the nation's stock of capital through crowding out of private investment.

The Medicare Shortfall The Medicare program is the U.S. health care program for people age 65 and older in the United States. The program costs \$510 billion per year and has been growing at about 9 percent annually. Like Social Security, it also is a pay-as-you-go plan, meaning that current medical benefits for people age 65 or older are being funded by current tax revenues from the 2.9 percent Medicare tax on earnings and the 3.8 percent investment surtax on wealthier investors that was instituted in 2013 as part of Obamacare. Like the Social Security tax, half the Medicare earnings tax is paid by the employer (1.45 percent) and half the by the employee. But the 2.9 percent Medicare tax is applied to all earnings.

The financial status of Medicare is much worse than that of Social Security. To begin with, the Medicare Trust Fund will be depleted in 2024, 9 years before the Social Security Trust Fund is expected to be depleted. Then, in subsequent years, the percentage of scheduled Medicare benefits covered by the Medicare tax will decline from 97 percent in 2025 to 72 percent in 2035 and 69 percent in 2080.

The Unpleasant Options To restore long-run balance to Social Security and Medicare, the federal government must either reduce benefits or increase revenues. It's as simple—and as complicated—as that! The Social Security Administration concludes that bringing projected Social Security revenues and payments into balance over the next 75 years would require a 16 percent permanent reduction in Social Security benefits, a 13 percent permanent increase in tax revenues, or some combination of the two. To bring projected Medicare revenues and expenses into long-run balance would require an increase in the Medicare payroll tax by 122 percent, a 51 percent reduction of Medicare payments from their projected levels, or some combination of each.

All the general options for closing all or part of the Social Security and Medicare gaps involve difficult economic trade-offs and dangerous political risks because one group or another will strongly oppose them. Here are just a few examples:

- Increasing the retirement age for collecting Social Security or Medicare benefits will upset preretirement workers who have been paying into the system and will receive their benefits later than they expected.
- Subjecting a larger portion of total earnings to the Social Security tax would constitute a gigantic tax increase on the earnings of the country's highest trained and educated individuals. This might reduce the incentive of younger people to obtain education and advance in their careers.
- Disqualifying wealthy individuals from receiving Social Security and Medicare benefits would tilt the programs toward welfare and redistribution, rather than insurance programs. This would undermine the broad existing political support for the programs.
- Redirecting legal immigration toward high-skilled, high-earning entrants and away from low-skilled, low-earning immigrants to raise Social Security and Medicare revenues would also raise the ire of some native-born high-skilled workers and the proponents of immigration based on family reunification.
- Placing the payroll tax revenues into accounts that individuals, not the government, would own, maintain, and bequeath would transform the Social Security and Medicare programs from guaranteed "defined benefit plans" into much riskier "defined contribution plans." The extreme short-run volatility of the stock market might leave some unlucky people destitute in old age.

The problem is huge and will not go away. One recent attempt to add up the underfunding of all the promised Social Security and Medicare benefits finds that the total underfunding greatly exceeds the combined current wealth (net worth) of everyone in the United States today.[†] Even if this estimate is somewhat extreme, the fact remains: The federal government and American people eventually will have to face up to the overpromising-underfunding problem and find ways to resolve it.

SUMMARY

L033.1 Identify and explain the purposes, tools, and limitations of fiscal policy.

Fiscal policy consists of deliberate changes in government spending, taxes, or some combination of both to promote full employment, price-level stability, and economic growth. Fiscal policy requires increases in government spending, decreases in taxes, or both—a budget deficit—to increase aggregate demand and push an economy from a recession. Decreases in government spending, increases in taxes, or both—a budget surplus—are appropriate fiscal policy for decreasing aggregate demand to try to slow or halt demand-pull inflation.

L033.2 Explain the role of built-in stabilizers in moderating business cycles.

Built-in stability arises from net tax revenues, which vary directly with the level of GDP. During recession, the federal budget automatically moves toward a stabilizing deficit; during expansion, the budget automatically moves toward an anti-inflationary surplus. Built-in stability lessens, but does not fully correct, undesired changes in real GDP.

L033.3 Describe how the cyclically adjusted budget reveals the status of U.S. fiscal policy.

Actual federal budget deficits can go up or down because of changes in GDP, changes in fiscal policy, or both. Deficits caused by changes in GDP are called cyclical deficits. The cyclically adjusted budget removes cyclical deficits from the budget and therefore measures the budget deficit or surplus that would occur if the economy operated at its full-employment output throughout the year. Changes in the cyclical budget deficit or surplus provide meaningful information as to whether the government's fiscal policy is expansionary, neutral, or contractionary. Changes in the actual budget deficit or surplus do not, since such deficits or surpluses can include cyclical deficits or surpluses.

L033.4 Summarize recent U.S. fiscal policy and the projections for U.S. fiscal policy over the next few years.

In 2001 the Bush administration and Congress chose to reduce marginal tax rates and phase out the federal estate tax. A recession occurred in 2001, and federal spending for the war on terrorism rocketed. The federal budget swung from a surplus of \$128 billion in 2001 to a deficit of \$158 billion in 2002. In 2003 the Bush administration and Congress accelerated the tax reductions scheduled under the 2001 tax law and cut tax rates on capital gains and dividends. The purposes were to stimulate a sluggish economy. By 2007 the economy had reached its full employment level of output.

The federal government responded to the deep recession of 2007–2009 by implementing highly expansionary fiscal policy. In 2008 the federal government passed a tax rebate program that sent \$600 checks to qualified individuals. Later that year, it created a \$700 billion emergency fund to keep key financial institutions from failing. These and other programs increased the cyclically adjusted budget deficit from -1.3 percent of potential GDP in 2007 to -2.9 percent in 2008. When the economy continued to plunge, the Obama administration and Congress enacted a massive \$787 billion stimulus program to be implemented over $2\frac{1}{2}$ years. The cyclically adjusted budget deficit shot up from -2.9 percent of potential GDP in 2008 to -7.1 percent in 2009, but then decreased to -1.6 percent in 2015.

L033.5 Discuss the problems that governments may encounter in enacting and applying fiscal policy.

Certain problems complicate the enactment and implementation of fiscal policy. They include (a) timing problems associated with recognition, administrative, and operational lags; (b) the potential for misuse of fiscal policy for political rather than economic purposes; (c) the fact that state and local finances tend to be pro-cyclical;

(d) potential ineffectiveness if households expect future policy reversals; and (e) the possibility of fiscal policy crowding out private investment.

Most economists believe that fiscal policy can help move the economy in a desired direction but cannot reliably be used to fine-tune the economy to a position of price stability and full employment. Nevertheless, fiscal policy is a valuable backup tool for aiding monetary policy in fighting significant recession or inflation.

L033.6 Discuss the size, composition, and consequences of the U.S. public debt.

The public debt is the total accumulation of all past federal government deficits and surpluses and consists of Treasury bills, Treasury notes, Treasury bonds, and U.S. savings bonds. In 2015 the U.S. public debt was \$18.2 trillion, or \$56,368 per person. The public (which here includes banks and state and local governments) holds 59 percent of that federal debt; the Federal Reserve and federal agencies hold the other 41 percent. Foreigners hold 34 percent of the federal debt. Interest payments as a percentage of GDP were about 2.2 percent in 2015.

Because of large deficits during the Great Recession and in subsequent years, the total U.S. public debt more than doubled between 2005 and 2015.

The concern that a large public debt may bankrupt the U.S. government is generally a false worry because (a) the debt needs only to be refinanced rather than refunded and (b) the federal government has the power to increase taxes to make interest payments on the debt.

In general, the public debt is not a vehicle for shifting economic burdens to future generations. Americans inherit not only most of the public debt (a liability) but also most of the U.S. government securities (an asset) that finance the debt.

More substantive problems associated with public debt include the following: (a) Payment of interest on the debt may increase income inequality. (b) Interest payments on the debt require higher taxes, which may impair incentives. (c) Paying interest or principal on the portion of the debt held by foreigners means a transfer of real output abroad. (d) Government borrowing to refinance or pay interest on the debt may increase interest rates and crowd out private investment spending, leaving future generations with a smaller stock of capital than they would have had otherwise.

The increase in investment in public capital that may result from debt financing may partly or wholly offset the crowding-out effect of the public debt on private investment. Also, the added public investment may stimulate private investment, where the two are complements.

DISCUSSION QUESTIONS

1. What is the role of the Council of Economic Advisers (CEA) as it relates to fiscal policy? Use an Internet search to find the names and university affiliations of the present members of the CEA. **L033.1**
2. What are government's fiscal policy options for ending severe demand-pull inflation? Which of these fiscal options do you think might be favored by a person who wants to preserve the size of government? A person who thinks the public sector is too large? How does the "ratchet effect" affect anti-inflationary fiscal policy? **L033.1**
3. (For students who were assigned Chapter 31) Use the aggregate expenditures model to show how government fiscal policy could eliminate either a recessionary expenditure gap or an inflationary expenditure gap (Figure 31.7). Explain how equal-size increases in G and T could eliminate a recessionary gap and how equal-size decreases in G and T could eliminate an inflationary gap. **L033.1**
4. Some politicians have suggested that the United States enact a constitutional amendment requiring that the federal government balance its budget annually. Explain why such an amendment, if strictly enforced, would force the government to enact a contractionary fiscal policy whenever the economy experienced a severe recession. **L033.1**
5. Explain how built-in (or automatic) stabilizers work. What are the differences between proportional, progressive, and regressive tax systems as they relate to an economy's built-in stability? **L033.2**
6. Define the cyclically adjusted budget, explain its significance, and state why it may differ from the actual budget. Suppose the full-employment, noninflationary level of real output is GDP_3 (not GDP_2) in the economy depicted in Figure 33.3. If the economy is operating at GDP_2 , instead of GDP_3 , what is the status of its cyclically adjusted budget? The status of its current fiscal policy? What change in fiscal policy would you recommend? How would you accomplish that in terms of the G and T lines in the figure? **L033.3**
7. Briefly state and evaluate the problem of time lags in enacting and applying fiscal policy. Explain the idea of a political business cycle. How might expectations of a near-term policy reversal weaken fiscal policy based on changes in tax rates? What is the crowding-out effect, and why might it be relevant to fiscal policy? In view of your answers, explain the following statement: "Although fiscal policy clearly is useful in combating the extremes of severe recession and demand-pull inflation, it is impossible to use fiscal policy to fine-tune the economy to the full-employment, noninflationary level of real GDP and keep the economy there indefinitely." **L033.5**
8. How do economists distinguish between the absolute and relative sizes of the public debt? Why is the distinction important? Distinguish between refinancing the debt and retiring the debt. How does an internally held public debt differ from an externally held public debt? Contrast the effects of retiring an internally held debt and retiring an externally held debt. **L033.6**
9. True or false? If false, explain why. **L033.6**
 - a. The total public debt is more relevant to an economy than the public debt as a percentage of GDP.
 - b. An internally held public debt is like a debt of the left hand owed to the right hand.
 - c. The Federal Reserve and federal government agencies hold more than three-fourths of the public debt.
 - d. The portion of the U.S. debt held by the public (and not by government entities) was larger as a percentage of GDP in 2015 than it was in 2000.
 - e. As a percentage of GDP, the total U.S. public debt is the highest such debt among the world's advanced industrial nations.
10. Why might economists be quite concerned if the annual interest payments on the U.S. public debt sharply increased as a percentage of GDP? **L033.6**
11. Trace the cause-and-effect chain through which financing and refinancing of the public debt might affect real interest rates, private investment, the stock of capital, and economic growth. How might investment in public capital and complementarities between public capital and private capital alter the outcome of the cause-effect chain? **L033.6**
12. **LAST WORD** What do economists mean when they say Social Security and Medicare are "pay-as-you-go" plans? What are the Social Security and Medicare trust funds, and how long will they have money left in them? What is the key long-run problem of both Social Security and Medicare? Do you favor increasing taxes or do you prefer reducing benefits to fix the problem?

REVIEW QUESTIONS

1. Which of the following would help a government reduce an inflationary output gap? **L033.1**
 - a. Raising taxes.
 - b. Lowering taxes.
 - c. Increasing government spending.
 - d. Decreasing government spending.
2. The economy is in a recession. A congresswoman suggests increasing spending to stimulate aggregate demand but also at the same time raising taxes to pay for the increased spending. Her suggestion to combine higher government expenditures with higher taxes is: **L033.1**
 - a. The worst possible combination of tax and expenditure changes.
 - b. The best possible combination of tax and expenditure changes.
 - c. A mediocre and contradictory combination of tax and expenditure changes.
 - d. None of the above.

3. During the recession of 2007–2009, the U.S. federal government's tax collections fell from about \$2.6 trillion down to about \$2.1 trillion while GDP declined by about 4 percent. Does the U.S. tax system appear to have built-in stabilizers? **L033.2**
- Yes.
 - No.
4. Last year, while an economy was in a recession, government spending was \$595 billion and government revenue was \$505 billion. Economists estimate that if the economy had been at its full-employment level of GDP last year, government spending would have been \$555 billion and government revenue would have been \$550 billion. Which of the following statements about this government's fiscal situation are true? **L033.3**
- The government has a non-cyclically adjusted budget deficit of \$595 billion.
 - The government has a non-cyclically adjusted budget deficit of \$90 billion.
 - The government has a non-cyclically adjusted budget surplus of \$90 billion.
 - The government has a cyclically adjusted budget deficit of \$555 billion.
 - The government has a cyclically adjusted budget deficit of \$5 billion.
 - The government has a cyclically adjusted budget surplus of \$5 billion.
5. Label each of the following scenarios in which there are problems enacting and applying fiscal policy as being an example

of either recognition lag, administrative lag, or operational lag.

L033.5

- To fight a recession, Congress has passed a bill to increase infrastructure spending—but the legally required environmental-impact statement for each new project will take at least two years to complete before any building can begin.
 - Distracted by a war that is going badly, politicians take no notice until inflation reaches 8 percent.
 - A sudden recession is recognized by politicians, but it takes many months of political deal making before a stimulus bill is finally approved.
 - To fight a recession, the president orders federal agencies to get rid of petty regulations that burden private businesses—but the federal agencies begin by spending a year developing a set of regulations on how to remove petty regulations.
6. In January, the interest rate is 5 percent and firms borrow \$50 billion per month for investment projects. In February, the federal government doubles its monthly borrowing from \$25 billion to \$50 billion. That drives the interest rate up to 7 percent. As a result, firms cut back their borrowing to only \$30 billion per month. Which of the following is true? **L033.6**
- There is no crowding-out effect because the government's increase in borrowing exceeds firms' decrease in borrowing.
 - There is a crowding-out effect of \$20 billion.
 - There is no crowding-out effect because both the government and firms are still borrowing a lot.
 - There is a crowding-out effect of \$25 billion.

PROBLEMS

1. Assume that a hypothetical economy with an MPC of .8 is experiencing severe recession. By how much would government spending have to rise to shift the aggregate demand curve rightward by \$25 billion? How large a tax cut would be needed to achieve the same increase in aggregate demand? Determine one possible combination of government spending increases and tax decreases that would accomplish the same goal. **L033.1**
2. Refer back to the table in Figure 32.7 in the previous chapter. Suppose that aggregate demand increases such that the amount of real output demanded rises by \$7 billion at each price level. By what percentage will the price level increase? Will this inflation be demand-pull inflation or will it be cost-push inflation? If potential real GDP (that is, full-employment GDP) is \$510 billion, what will be the size of the positive GDP gap after the change in aggregate demand? If government wants to use fiscal policy to counter the resulting inflation without changing tax rates, would it increase government spending or decrease it? **L033.1**
3. (For students who were assigned Chapter 31) Assume that, without taxes, the consumption schedule for an economy is as shown below: **L033.1**

GDP, Billions	Consumption, Billions
\$100	\$120
200	200
300	280
400	360
500	440
600	520
700	600

- Graph this consumption schedule. What is the size of the MPC?
- Assume that a lump-sum (regressive) tax of \$10 billion is imposed at all levels of GDP. Calculate the tax rate at each level of GDP. Graph the resulting consumption schedule and compare the MPC and the multiplier with those of the pretax consumption schedule.
- Now suppose a proportional tax with a 10 percent tax rate is imposed instead of the regressive tax. Calculate and graph the new consumption schedule and note the MPC and the multiplier.

- d. Finally, impose a progressive tax such that the tax rate is 0 percent when GDP is \$100, 5 percent at \$200, 10 percent at \$300, 15 percent at \$400, and so forth. Determine and graph the new consumption schedule, noting the effect of this tax system on the MPC and the multiplier.
- e. Use a graph similar to Figure 33.3 to show why proportional and progressive taxes contribute to greater economic stability, while a regressive tax does not.
4. Refer to the following table for Waxwania: **L033.2**

Government Expenditures, G	Tax Revenues, T	Real GDP
\$160	\$100	\$500
160	120	600
160	140	700
160	160	800
160	180	900

What is the marginal tax rate in Waxwania? The average tax rate? Which of the following describes the tax system: proportional, progressive, regressive?

5. Refer to the table for Waxwania in problem 4. Suppose that Waxwania is producing \$600 of real GDP, whereas the potential real GDP (or full-employment real GDP) is \$700. How large is its budget deficit? Its cyclically adjusted budget deficit? Its cyclically adjusted budget deficit as a percentage of potential real GDP? Is Waxwania's fiscal policy expansionary or is it contractionary? **L033.3**
6. Suppose that a country has no public debt in year 1 but experiences a budget deficit of \$40 billion in year 2, a budget surplus of \$10 billion in year 3, and a budget deficit of \$2 billion in year 4. What is the absolute size of its public debt in year 4? If its real GDP in year 4 is \$104 billion, what is this country's public debt as a percentage of real GDP in year 4? **L033.6**
7. Suppose that the investment demand curve in a certain economy is such that investment declines by \$100 billion for every 1 percentage point increase in the real interest rate. Also, suppose that the investment demand curve shifts rightward by \$150 billion at each real interest rate for every 1 percentage point increase in the expected rate of return from investment. If stimulus spending (an expansionary fiscal policy) by government increases the real interest rate by 2 percentage points, but also raises the expected rate of return on investment by 1 percentage point, how much investment, if any, will be crowded out? **L033.6**

Money is a fascinating aspect of the economy:

Money bewitches people. They fret for it, and they sweat for it. They devise most ingenious ways to get it, and most ingenuous ways to get rid of it. Money is the only commodity that is good for nothing but to be gotten rid of. It will not feed you, clothe you, shelter you, or amuse you unless you spend it or invest it. It imparts value only in parting. People will do almost anything for money, and money will do almost anything for people. Money is a captivating, circulating, masquerading puzzle.¹

In this chapter and the two chapters that follow, we want to unmask the critical role of money and the monetary system in the economy. When the monetary system is working properly, it provides the lifeblood of the circular flows of

income and expenditure. A well-operating monetary system helps the economy achieve both full employment and the efficient use of resources. A malfunctioning monetary

system distorts the allocation of resources and creates severe fluctuations in the economy's levels of output, employment, and prices.

The Functions of Money

L034.1 Identify and explain the functions of money.

Just what is money? There is an old saying that “money *is* what money *does*.” In a general sense, anything that performs the functions of money *is* money. Here are those functions:

- **Medium of exchange** First and foremost, money is a **medium of exchange** that is usable for buying and selling goods and services. A bakery worker does not want to be paid 200 bagels per week. Nor does the bakery owner want to receive, say, halibut in exchange for bagels. Money, however, is readily acceptable as payment. As we saw in Chapter 2, money is a social invention with which resource suppliers and producers can be paid and that can be used to buy any of the full range of items available in the marketplace. As a medium of exchange, money allows society to escape the complications of barter. And because it provides a convenient way of exchanging goods, money enables society to gain the advantages of geographic and human specialization.
- **Unit of account** Money is also a **unit of account**. Society uses monetary units—dollars, in the United States—as a yardstick for measuring the relative worth of a wide variety of goods, services, and resources. Just as we measure distance in miles or kilometers, we gauge the value of goods in dollars.

With money as an acceptable unit of account, the price of each item need be stated only in terms of the monetary unit. We need not state the price of cows in terms of corn, crayons, and cranberries. Money aids rational decision making by enabling buyers and sellers to easily compare the prices of various goods, services, and resources. It also permits us to define debt obligations, determine taxes owed, and calculate the nation's GDP.

- **Store of value** Money also serves as a **store of value** that enables people to transfer purchasing power from the present to the future. People normally do not spend all their incomes on the day they receive them. To buy things later, they store some of their wealth as money. The money you place in a safe or a checking account will still be available to you a few weeks or months from now. When inflation is nonexistent or mild, holding money is a relatively risk-free way to store your wealth for later use.

People can, of course, choose to hold some or all of their wealth in a wide variety of assets besides money. These include real estate, stocks, bonds, precious metals such as gold,

and even collectible items like fine art or comic books. But a key advantage that money has over all other assets is that it has the most *liquidity*, or spendability.

An asset's **liquidity** is the ease with which it can be converted quickly into the most widely accepted and easily spent form of money, cash, with little or no loss of purchasing power. The more liquid an asset is, the more quickly it can be converted into cash and used for either purchases of goods and services or purchases of other assets.

Levels of liquidity vary radically. By definition, cash is perfectly liquid. By contrast, a house is highly illiquid for two reasons. First, it may take several months before a willing buyer can be found and a sale negotiated so that its value can be converted into cash. Second, there is a loss of purchasing power when the house is sold because numerous fees have to be paid to real estate agents and other individuals to complete the sale.

As we are about to discuss, our economy uses several different types of money including cash, coins, checking account deposits, savings account deposits, and even more exotic things like deposits in money market mutual funds. As we describe the various forms of money in detail, take the time to compare their relative levels of liquidity—both with each other and as compared to other assets like stocks, bonds, and real estate. Cash is perfectly liquid. Other forms of money are highly liquid, but less liquid than cash.

The Components of the Money Supply

L034.2 List and describe the components of the U.S. money supply.

Money is a “stock” of some item or group of items (unlike income, for example, which is a “flow”). Societies have used many items as money, including whales' teeth, circular stones, elephant-tail bristles, gold coins, furs, and pieces of paper. Anything that is widely accepted as a medium of exchange can serve as money. In the United States, currency is not the only form of money. As you will see, certain debts of government and financial institutions also are used as money.

Money Definition M1

The narrowest definition of the U.S. money supply is called **M1**. It consists of two components:

- Currency (coins and paper money) in the hands of the public.

- All checkable deposits (all deposits in commercial banks and “thrift” or savings institutions on which checks of any size can be drawn).²

Government and government agencies supply coins and paper money. Commercial banks (“banks”) and savings institutions (“thrifts”) provide checkable deposits. Figure 34.1a shows that *M1* is about equally divided between the two components.

Currency: Coins + Paper Money The currency of the United States consists of metal coins and paper money. The coins are issued by the U.S. Treasury while the paper money consists of **Federal Reserve Notes** issued by the Federal Reserve System (the U.S. central bank). The coins are minted by the U.S. Mint, while the paper money is printed by the Bureau of Engraving and Printing. Both the U.S. Mint and the Bureau of Engraving and Printing are part of the U.S. Department of the Treasury.

As with the currencies of other countries, the currency of the United States is **token money**. This means that the face

²In the ensuing discussion, we do not discuss several of the quantitatively less significant components of the definitions of money to avoid a maze of details. For example, traveler’s checks are included in the *M1* money supply. The statistical appendix of any recent *Federal Reserve Bulletin* provides more comprehensive definitions.

value of any piece of currency is unrelated to its *intrinsic value*—the value of the physical material (metal or paper and ink) out of which that piece of currency is constructed. Governments make sure that face values exceed intrinsic values to discourage people from destroying coins and bills to resell the material that they are made out of. For instance, if 50-cent pieces each contained 75 cents’ worth of metal, then it would be profitable to melt them down and sell the metal. Fifty-cent pieces would disappear from circulation very quickly!

Figure 34.1a shows that currency (coins and paper money) constitutes 43 percent of the *M1* money supply in the United States.

Checkable Deposits The safety and convenience of checks has made **checkable deposits** a large component of the *M1* money supply. You would not think of stuffing \$4,896 in bills in an envelope and dropping it in a mailbox to pay a debt. But writing and mailing a check for a large sum is commonplace. The person cashing a check must endorse it (sign it on the reverse side); the writer of the check subsequently receives a record of the cashed check as a receipt attesting to the fulfillment of the obligation. Similarly, because the writing of a check requires endorsement, the theft or loss of your checkbook is not nearly as calamitous as losing an identical amount of currency. Finally, it is more convenient to write a

FIGURE 34.1 Components of money supply *M1* and money supply *M2*, in the United States. (a) *M1* is a narrow definition of the money supply that includes currency (in circulation) and checkable deposits. (b) *M2* is a broader definition that includes *M1* along with several other relatively liquid account balances.

check than to transport and count out a large sum of currency. For all these reasons, checkable deposits (checkbook money) are a large component of the stock of money in the United States. About 57 percent of *M1* is in the form of checkable deposits, on which checks can be drawn.

It might seem strange that checking account balances are regarded as part of the money supply. But the reason is clear: Checks are nothing more than a way to transfer the ownership of deposits in banks and other financial institutions and are generally acceptable as a medium of exchange. Although checks are less generally accepted than currency for small purchases, for major purchases most sellers willingly accept checks as payment. Moreover, people can convert checkable deposits into paper money and coins on demand; checks drawn on those deposits are thus the equivalent of currency.

To summarize:

Money, *M1* = currency + checkable deposits

Institutions That Offer Checkable Deposits In the United States, a variety of financial institutions allow customers to write checks in any amount on the funds they have deposited. **Commercial banks** are the primary depository institutions. They accept the deposits of households and businesses, keep the money safe until it is demanded via checks, and in the meantime use it to make available a wide variety of loans. Commercial bank loans provide short-term financial capital to businesses, and they finance consumer purchases of automobiles and other durable goods.

Savings and loan associations (S&Ls), mutual savings banks, and credit unions supplement the commercial banks and are known collectively as savings or **thrift institutions**, or simply “thrifts.” *Savings and loan associations* and *mutual savings banks* accept the deposits of households and businesses and then use the funds to finance housing mortgages and to provide other loans. *Credit unions* accept deposits from and lend to “members,” who usually are a group of people who work for the same company.

The checkable deposits of banks and thrifts are known variously as demand deposits, NOW (negotiable order of withdrawal) accounts, ATS (automatic transfer service) accounts, and share draft accounts. Their commonality is that depositors can write checks on them whenever, and in whatever amount, they choose.

Two Qualifications We must qualify our discussion in two important ways. First, currency held by the U.S. Treasury, the Federal Reserve banks, commercial banks, and thrift institutions is *excluded* from *M1* and other measures of the money supply. A paper dollar or four quarters in the billfold of, say, Emma Buck obviously constitutes just \$1 of the money supply. But if we counted currency held by banks as part of the money supply, the same \$1 would count for \$2 of money supply when Emma deposited the currency into her checkable deposit in her bank. It would count for \$1 of checkable deposit owned by

Buck and also \$1 of currency in the bank’s cash drawer or vault. By excluding currency held by banks when determining the total supply of money, we avoid this problem of double counting.

Also *excluded* from the money supply are any checkable deposits of the government (specifically, the U.S. Treasury) or the Federal Reserve that are held by commercial banks or thrift institutions. This exclusion is designed to enable a better assessment of the amount of money available *to the private sector* for potential spending. The amount of money available to households and businesses is of keen interest to the Federal Reserve in conducting its monetary policy (a topic we cover in detail in Chapter 36).

Money Definition *M2*

A second and broader definition of money includes *M1* plus several near-monies. **Near-monies** are certain highly liquid financial assets that do not function directly or fully as a medium of exchange but can be readily converted into currency or checkable deposits. The *M2* definition of money includes three categories of near-monies.

- **Savings deposits, including money market deposit accounts** A depositor can easily withdraw funds from a **savings account** at a bank or thrift or simply request that the funds be transferred from a savings account to a checkable account. A person can also withdraw funds from a **money market deposit account (MMDA)**, which is an interest-bearing account containing a variety of interest-bearing short-term securities. MMDAs, however, have a minimum-balance requirement and a limit on how often a person can withdraw funds.
- **Small-denominated (less than \$100,000) time deposits** Funds from **time deposits** become available at their maturity. For example, a person can convert a 6-month time deposit (“certificate of deposit,” or “CD”) to currency without penalty 6 months or more after it has been deposited. In return for this withdrawal limitation, the financial institution pays a higher interest rate on such deposits than it does on its MMDAs. Also, a person can “cash in” a CD at any time but must pay a severe penalty.
- **Money market mutual funds held by individuals** By making a telephone call, using the Internet, or writing a check for \$500 or more, a depositor can redeem shares in a **money market mutual fund (MMMF)** offered by a mutual fund company. Such companies use the combined funds of individual shareholders to buy interest-bearing short-term credit instruments such as certificates of deposit and U.S. government securities. Then they can offer interest on the MMMF accounts of the shareholders (depositors) who jointly own those financial assets. The MMMFs in *M2* include only the MMMF accounts held by individuals; those held by businesses and other institutions are excluded.

Are Credit Cards Money?

You may wonder why we have ignored credit cards such as Visa and MasterCard in our discussion of how the money supply is defined. After all, credit cards are a convenient way to buy

things and account for about 25 percent of the dollar value of all transactions in the United States. The answer is that a credit card is not money. Rather, it is a convenient means of obtaining a short-term loan from the financial institution that issued the card.

What happens when you purchase an item with a credit card? The bank that issued the card will reimburse the seller by making a money payment and charging the establishment a transaction fee, and later you will reimburse the bank for its loan to you by also making a money payment. Rather than reduce your cash or checking account with each purchase, you bunch your payments once a month. You may have to pay an annual fee for the services provided, and if you pay the bank in installments, you will pay a sizable interest charge on the loan. Credit cards are merely a means of deferring or postponing payment for a short period. Your checking account balance that you use to pay your credit card bill *is* money; the credit card is *not* money.*

Although credit cards are not money, they allow individuals and businesses to “economize” in the use of money. Credit cards enable people to hold less currency in their billfolds and, prior to payment due dates, fewer checkable deposits in their bank accounts. Credit cards also help people coordinate the timing of their expenditures with their receipt of income.

*A bank debit card, however, is very similar to a check in your checkbook. Unlike a purchase with a credit card, a purchase with a debit card creates a direct “debit” (a subtraction) from your checking account balance. That checking account balance is money—it is part of *M1*.

All three categories of near-monies imply substantial liquidity. Thus, in equation form,

$$\text{Money, } M_2 = M_1 + \text{savings deposits, including} \\ \text{MMDAs} + \text{small-denominated} \\ \text{(less than \$100,000) time deposits} \\ + \text{MMMFs held by individuals}$$

In summary, *M2* includes the immediate medium-of-exchange items (currency and checkable deposits) that constitute *M1* plus certain near-monies that can be easily converted into

currency and checkable deposits. In Figure 34.1b, we see that the addition of all these items yields an *M2* money supply that is about five times larger than the narrower *M1* money supply.

QUICK REVIEW 34.1

- ✓ Money serves as a medium of exchange, a unit of account, and a store of value.
- ✓ The narrow *M1* definition of money includes currency held by the public plus checkable deposits in commercial banks and thrift institutions.
- ✓ Thrift institutions, as well as commercial banks, offer accounts on which checks can be written.
- ✓ The *M2* definition of money includes *M1* plus savings deposits, including money market deposit accounts, small-denominated (less than \$100,000) time deposits, and money market mutual fund balances held by individuals.

What “Backs” the Money Supply?

L034.3 Describe what “backs” the money supply, making us willing to accept it as payment.

The money supply in the United States essentially is “backed” (guaranteed) by the government’s ability to keep the value of money relatively stable. Nothing more!

Money as Debt

The major components of the money supply—paper money and checkable deposits—are debts, or promises to pay. In the United States, paper money is the circulating debt of the Federal Reserve Banks. Checkable deposits are the debts of commercial banks and thrift institutions.

Paper currency and checkable deposits have no intrinsic value. A \$5 bill is just an inscribed piece of paper. A checkable deposit is merely a bookkeeping entry. And coins, we know, have less intrinsic value than their face value. Nor will government redeem the paper money you hold for anything tangible, such as gold. To many people, the fact that the government does not back the currency with anything tangible seems implausible and insecure. But the decision not to back the currency with anything tangible was made for a very good reason. If the government backed the currency with something tangible like gold, then the supply of money would vary with how much gold was available. By not backing the currency, the government avoids this constraint and indeed receives a key freedom—the ability to provide as much or as little money as needed to maintain the value of money and to best suit the economic needs of the country. In effect, by choosing not to back the currency, the government has chosen to give itself the ability to freely “manage” the nation’s money supply. Its monetary authorities attempt to provide the

amount of money needed for the particular volume of business activity that will promote full employment, price-level stability, and economic growth.

Nearly all today's economists agree that managing the money supply is more sensible than linking it to gold or to some other commodity whose supply might change arbitrarily and capriciously. For instance, if we used gold to back the money supply so that gold was redeemable for money and vice versa, then a large increase in the nation's gold stock as the result of a new gold discovery might increase the money supply too rapidly and thereby trigger rapid inflation. Or a long-lasting decline in gold production might reduce the money supply to the point where recession and unemployment resulted.

In short, people cannot convert paper money into a fixed amount of gold or any other precious commodity. Money is exchangeable only for paper money. If you ask the government to redeem \$5 of your paper money, it will swap one paper \$5 bill for another bearing a different serial number. That is all you can get. Similarly, checkable deposits can be redeemed not for gold but only for paper money, which, as we have just seen, the government will not redeem for anything tangible.

Value of Money

So why are currency and checkable deposits money, whereas, say, Monopoly (the game) money is not? What gives a \$20 bill or a \$100 checking account entry its value? The answer to these questions has three parts.

Acceptability Currency and checkable deposits are money because people accept them as money. By virtue of long-standing business practice, currency and checkable deposits perform the basic function of money: They are acceptable as a medium of exchange. We accept paper money in exchange because we are confident it will be exchangeable for real goods, services, and resources when we spend it.

Legal Tender Our confidence in the acceptability of paper money is strengthened because the government has designated currency as **legal tender**. Specifically, each bill contains the statement "This note is legal tender for all debts, public and private." That means paper money is a valid and legal means of payment of any debt that was contracted in dollars. (But private firms and government are not mandated to accept cash. It is not illegal for them to specify payment in noncash forms such as checks, cashier's checks, money orders, or credit cards.)

The general acceptance of paper currency in exchange is more important than the government's decree that money is legal tender, however. The government has never decreed checks to be legal tender, and yet they serve as such in many of the economy's exchanges of goods, services, and resources. But it is true that government agencies—the Federal Deposit

Insurance Corporation (FDIC) and the National Credit Union Administration (NCUA)—insure individual deposits of up to \$250,000 at commercial banks and thrifts. That fact enhances our willingness to use checkable deposits as a medium of exchange.

Relative Scarcity The value of money, like the economic value of anything else, depends on its supply and demand. Money derives its value from its scarcity relative to its utility (its want-satisfying power). The utility of money lies in its capacity to be exchanged for goods and services, now or in the future. The economy's demand for money thus depends on the total dollar volume of transactions in any period plus the amount of money individuals and businesses want to hold for future transactions. With a reasonably constant demand for money, the supply of money provided by the monetary authorities will determine the domestic value or "purchasing power" of the monetary unit (dollar, yen, peso, or whatever).

Money and Prices

The purchasing power of money is the amount of goods and services a unit of money will buy. When money rapidly loses its purchasing power, it loses its role as money.

The Purchasing Power of the Dollar The amount a dollar will buy varies inversely with the price level; that is, a reciprocal relationship exists between the general price level and the purchasing power of the dollar. When the consumer price index or "cost-of-living" index goes up, the value of the dollar goes down, and vice versa. Higher prices lower the value of the dollar because more dollars are needed to buy a particular amount of goods, services, or resources. For example, if the price level doubles, the value of the dollar declines by one-half, or 50 percent.

Conversely, lower prices increase the purchasing power of the dollar because fewer dollars are needed to obtain a specific quantity of goods and services. If the price level falls by, say, one-half, or 50 percent, the purchasing power of the dollar doubles.

In equation form, the relationship looks like this:

$$\$V = 1/P$$

To find the value of the dollar $\$V$, divide 1 by the price level P expressed as an index number (in hundredths). If the price level is 1, then the value of the dollar is 1. If the price level rises to, say, 1.20, $\$V$ falls to 0.833; a 20 percent increase in the price level reduces the value of the dollar by 16.67 percent. Check your understanding of this reciprocal relationship by determining the value of $\$V$ and its percentage rise when P falls by 20 percent from \$1 to 0.80.

Inflation and Acceptability In Chapter 29 we noted situations in which a nation's currency became worthless and

unacceptable in exchange. These instances of runaway inflation, or *hyperinflation*, happened when the government issued so many pieces of paper currency that the purchasing power of each of those units of money was almost totally undermined. The infamous post–World War I hyperinflation in Germany is an example. In December 1919 there were about 50 billion marks in circulation. Four years later there were 496,585,345,900 billion marks in circulation! The result? The German mark in 1923 was worth an infinitesimal fraction of its 1919 value.³

Runaway inflation may significantly depreciate the value of money between the time it is received and the time it is spent. Rapid declines in the value of a currency may cause it to cease being used as a medium of exchange. Businesses and households may refuse to accept paper money in exchange because they do not want to bear the loss in its value that will occur while it is in their possession. (All this despite the fact that the government says that paper currency is legal tender!) Without an acceptable domestic medium of exchange, the economy may simply revert to barter. Alternatively, more stable currencies such as the U.S. dollar or European euro may come into widespread use. At the extreme, a country may adopt a foreign currency as its own official currency as a way to counter hyperinflation.

Similarly, people will use money as a store of value only as long as there is no sizable deterioration in the value of that money because of inflation. And an economy can effectively employ money as a unit of account only when its purchasing power is relatively stable. A monetary yardstick that no longer measures a yard (in terms of purchasing power) does not permit buyers and sellers to establish the terms of trade clearly. When the value of the dollar is declining rapidly, sellers do not know what to charge and buyers do not know what to pay.

Stabilizing Money's Purchasing Power

Rapidly rising price levels (rapid inflation) and the consequent erosion of the purchasing power of money typically result from imprudent economic policies. Since the purchasing power of money and the price level vary inversely, stabilization of the purchasing power of a nation's money requires stabilization of the nation's price level. Such price-level stability (2 to 3 percent annual inflation) mainly necessitates intelligent management or regulation of the nation's money supply and interest rates (*monetary policy*). It also requires appropriate *fiscal policy* supportive of the efforts of the nation's monetary authorities to hold down inflation. In the United States, a combination of legislation, government policy, and social practice inhibits imprudent expansion of the money supply that might jeopardize money's purchasing power. The critical role of the U.S. monetary authorities (the Federal Reserve) in

maintaining the purchasing power of the dollar is the subject of Chapter 36. For now, simply note that they make available a particular quantity of money, such as *M2* in Figure 34.1, and can change that amount through their policy tools.

QUICK REVIEW 34.2

- ✓ In the United States, all money consists essentially of the debts of government, commercial banks, and thrift institutions.
- ✓ These debts efficiently perform the functions of money as long as their value, or purchasing power, is relatively stable.
- ✓ The value of money is rooted not in specified quantities of precious metals but in the amounts of goods, services, and resources that money will purchase.
- ✓ The value of the dollar (its domestic purchasing power) is inversely related to the price level.
- ✓ Government's responsibility in stabilizing the purchasing power of the monetary unit calls for (a) effective control over the supply of money by the monetary authorities and (b) the application of appropriate fiscal policies by the president and Congress.

The Federal Reserve and the Banking System

L034.4 Discuss the makeup of the Federal Reserve and its relationship to banks and thrifts.

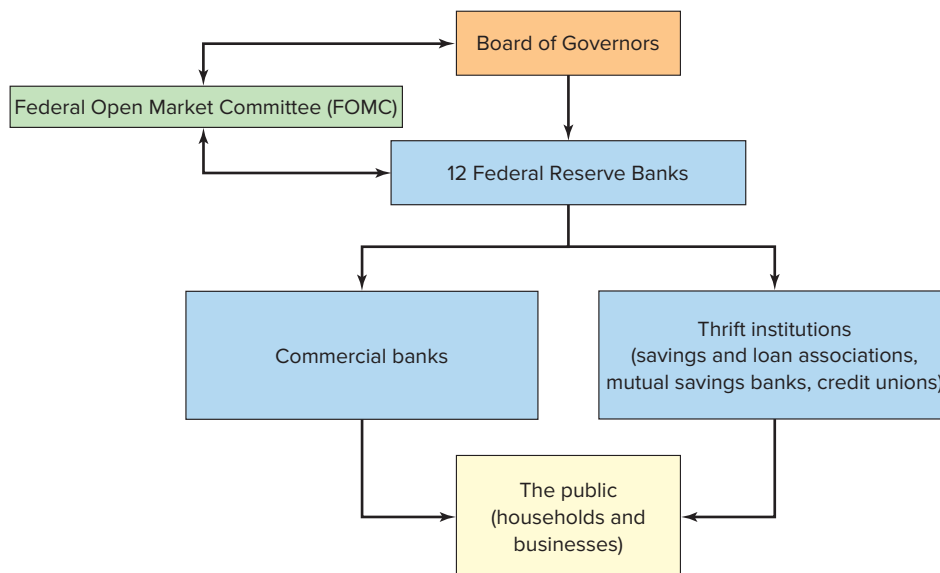

In the United States, the “monetary authorities” we have been referring to are the members of the Board of Governors of the **Federal Reserve System** (the “Fed”). As shown in Figure 34.2, the Board directs the activities of the 12 Federal Reserve Banks, which in turn control the lending activity of the nation's banks and thrift institutions. The Fed's major goal is to control the money supply. But since checkable deposits in banks are such a large part of the money supply, an important part of its duties involves assuring the stability of the banking system.

Historical Background

Early in the twentieth century, Congress decided that centralization and public control were essential for an efficient banking system. Decentralized, unregulated banking had fostered the inconvenience and confusion of numerous private bank notes being used as currency. It also had resulted in occasional episodes of monetary mismanagement such that the money supply was inappropriate to the needs of the economy. Sometimes “too much” money precipitated rapid inflation; other times “too little money” stunted the economy's growth by hindering the production and exchange of goods and services. No single entity was charged with creating and implementing nationally consistent banking policies.

³Frank G. Graham, *Exchange, Prices, and Production in Hyperinflation Germany, 1920–1923* (Princeton, NJ: Princeton University Press, 1930), p. 13.

FIGURE 34.2 Framework of the Federal Reserve System and its relationship to the public. The Board of Governors makes the basic policy decisions that provide monetary control of the U.S. money and banking systems. The 12 Federal Reserve Banks implement these decisions. Both the Board of Governors and the 12 Federal Reserve Banks are aided by the Federal Open Market Committee (FOMC).

Furthermore, acute problems in the banking system occasionally erupted when banks either closed down or insisted on immediate repayment of loans to prevent their own failure. At such times, a banking crisis could emerge, with individuals and businesses who had lost confidence in their banks attempting to simultaneously withdraw all of their money—thereby further crippling the already weakened banks.

An unusually acute banking crisis in 1907 motivated Congress to appoint the National Monetary Commission to study the monetary and banking problems of the economy and to outline a course of action for Congress. The result was the Federal Reserve Act of 1913.

Let's examine the various parts of the Federal Reserve System and their relationship to one another.

Board of Governors

The central authority of the U.S. money and banking system is the **Board of Governors** of the Federal Reserve System. The U.S. president, with the confirmation of the Senate, appoints the seven Board members. Terms are 14 years and staggered so that one member is replaced every 2 years. In addition, new members are appointed when resignations occur. The president selects the chairperson and vice chairperson of the Board from among the members. Those officers serve 4-year terms and can be reappointed to new 4-year terms by the president. The long-term appointments provide the Board with continuity, experienced membership, and independence from political pressures that could result in inflation.

The 12 Federal Reserve Banks

The 12 **Federal Reserve Banks**, which blend private and public control, collectively serve as the nation's "central bank." These banks also serve as bankers' banks.

Central Bank Most nations have a single central bank—for example, Britain's Bank of England or Japan's Bank of Japan. The United States' central bank consists of 12 banks whose policies are coordinated by the Fed's Board of Governors. The 12 Federal Reserve Banks accommodate the geographic size and economic diversity of the United States and the nation's large number of commercial banks and thrifts.

Figure 34.3 locates the 12 Federal Reserve Banks and indicates the district that each serves. These banks implement the basic policy of the Board of Governors.

Quasi-Public Banks The 12 Federal Reserve Banks are quasi-public banks, which blend private ownership and public control. Each Federal Reserve Bank is owned by the private commercial banks in its district. (Federally chartered banks are required to purchase shares of stock in the Federal Reserve Bank in their district.) But the Board of Governors, a government body, sets the basic policies that the Federal Reserve Banks pursue.

Despite their private ownership, the Federal Reserve Banks are in practice public institutions. Unlike private firms, they are not motivated by profit. The policies they follow are designed by the Board of Governors to promote the well-being of the economy as a whole. Thus, the activities of the Federal Reserve Banks are frequently at odds with the profit motive.⁴ Also, the Federal Reserve Banks do not compete with commercial banks. In general, they do not deal with the public; rather, they interact with the government and commercial banks and thrifts.

⁴Although it is not their goal, the Federal Reserve Banks have actually operated profitably, largely as a result of the Treasury debts they hold. Part of the profit is used to pay 6 percent annual dividends to the commercial banks that hold stock in the Federal Reserve Banks; the remaining profit is usually turned over to the U.S. Treasury.

FIGURE 34.3 The 12 Federal Reserve Districts. The Federal Reserve System divides the United States into 12 districts, each having one central bank and, in some instances, one or more branches of the central bank.

Bankers' Banks The Federal Reserve Banks are "bankers' banks." They perform essentially the same functions for banks and thrifts as those institutions perform for the public. Just as banks and thrifts accept the deposits of and make loans to the public, so the central banks accept the deposits of and make loans to banks and thrifts. Normally, these loans average only about \$150 million a day. But in emergency circumstances the Federal Reserve Banks become the "lender of last resort" to the banking system and can lend out as much as needed to ensure that banks and thrifts can meet their cash obligations. On the day after terrorists attacked the United States on September 11, 2001, the Fed lent \$45 billion to U.S. banks and thrifts. The Fed wanted to make sure that the destruction and disruption in New York City and the Washington, D.C., area did not precipitate a nationwide banking crisis.

The Fed assumed an even greater role as a lender of last resort during the financial crisis of 2007–2008. We discuss that crisis and the Fed's emergency response to the crisis later in this chapter.

But the Federal Reserve Banks have a third function, which banks and thrifts do not perform: They issue currency. Congress has authorized the Federal Reserve Banks to put into circulation Federal Reserve Notes, which constitute the economy's paper money supply.

FOMC

The **Federal Open Market Committee (FOMC)** aids the Board of Governors in conducting monetary policy. The FOMC is made up of 12 individuals:

- The seven members of the Board of Governors.
- The president of the New York Federal Reserve Bank.

- Four of the remaining presidents of Federal Reserve Banks on a 1-year rotating basis.

The FOMC meets regularly to direct the purchase and sale of government securities (bills, notes, bonds) in the open market in which such securities are bought and sold on a daily basis. The FOMC also makes decisions about borrowing and lending government securities in the open market. We will find in Chapter 36 that the purpose of these aptly named *open-market operations* is to control the nation's money supply and influence interest rates. The Federal Reserve Bank in New York City conducts most of the Fed's open-market operations.

Commercial Banks and Thrifts

There are about 6,000 commercial banks. Roughly three-fourths are state banks. These are private banks chartered (authorized) by the individual states to operate within those states. One-fourth are private banks chartered by the federal government to operate nationally; these are national banks. Some of the U.S. national banks are very large, ranking among the world's largest financial institutions (see Global Perspective 34.1).

The 8,500 thrift institutions—most of which are credit unions—are regulated by agencies in addition to the Board of Governors and the Federal Reserve Banks. For example, credit unions are regulated and monitored by the National Credit Union Administration (NCUA). But the thrifts *are* subject to monetary control by the Federal Reserve System. In particular, like the banks, thrifts are required to keep a certain percentage of their checkable deposits as "reserves."

In Figure 34.2, we use arrows to indicate that the thrift institutions are subject to the control of the Board of Governors and the central banks. Decisions concerning monetary policy affect the thrifts along with the commercial banks.

Fed Functions, Responsibilities, and Independence

LO34.5 Identify the functions and responsibilities of the Federal Reserve and explain why Fed independence is important.

The Fed performs several functions, some of which we have already identified, but they are worth repeating:

- **Issuing currency** The Federal Reserve Banks issue Federal Reserve Notes, the paper currency used in the U.S. monetary system. (The Federal Reserve Bank that issued a particular bill is identified in black in the upper left of the front of the newly designed bills. "A1," for example, identifies the Boston bank, "B2" the New York bank, and so on.)
- **Setting reserve requirements and holding reserves** The Fed sets reserve requirements, which are the fractions of checking account balances that banks must maintain as currency reserves. The central banks accept as deposits

from the banks and thrifts any portion of their mandated reserves not held as vault cash.

- **Lending to financial institutions and serving as an emergency lender of last resort** The Fed makes routine short-term loans to banks and thrifts and charges them an interest rate called the *discount rate*. It also occasionally auctions off loans to banks and thrifts through its *Term Auction Facility*, discussed in Chapter 36. In times of financial emergencies, the Fed serves as a lender of last resort to critical parts of the U.S. financial industry.
- **Providing for check collection** The Fed provides the banking system with a means for collecting on checks. If Sue writes a check on her Miami bank or thrift to Joe, who deposits it in his Dallas bank or thrift, how does the Dallas bank collect the money represented by the check drawn against the Miami bank? Answer: The Fed handles it by adjusting the reserves (deposits) of the two banks.
- **Acting as fiscal agent** The Fed acts as the fiscal agent (provider of financial services) for the federal government. The government collects huge sums through taxation, spends equally large amounts, and sells and redeems bonds. To carry out these activities, the government uses the Fed's facilities.
- **Supervising banks** The Fed supervises the operations of banks. It makes periodic examinations to assess bank profitability, to ascertain that banks perform in accordance with the many regulations to which they are subject, and to uncover questionable practices or fraud. Following the financial crisis of 2007–2008, Congress expanded the Fed's supervisory powers over banks.⁵
- **Controlling the money supply** Finally, the Fed has ultimate responsibility for regulating the supply of money, and this enables it to influence interest rates. The major task of the Fed under usual economic circumstances is to manage the money supply (and thus interest rates) according to the needs of the economy. This involves making an amount of money available that is consistent with high and rising levels of output and employment *and* a relatively stable price level. While most of the other functions of the Fed are routine activities or have a service nature, managing the nation's money supply requires making basic, but unique, policy decisions. (We discuss those decisions in detail in Chapter 36.)

⁵The Fed is not alone in this task of supervision. The individual states supervise the banks that they charter. The Office of the Comptroller of the Currency has separate supervisory authority over the banks and the thrifts. Also, the Federal Deposit Insurance Corporation supervises the banks and thrifts whose deposits it insures.

Federal Reserve Independence

Congress purposely established the Fed as an independent agency of government. The objective was to protect the Fed from political pressures so that it could effectively control the money supply and maintain price stability. Political pressures on Congress and the executive branch may at times result in inflationary fiscal policies, including tax cuts and special-interest spending. If Congress and the executive branch also controlled the nation's monetary policy, citizens and lobbying groups undoubtedly would pressure elected officials to keep interest rates low even though at times high interest rates are necessary to reduce aggregate demand and thus control inflation. An independent monetary authority (the Fed) can take actions to increase interest rates when higher rates are needed to stem inflation. Studies show that countries that have independent central banks like the Fed have lower rates of inflation, on average, than countries that have little or no central bank independence.

The Financial Crisis of 2007 and 2008

LO34.6 Identify and explain the main factors that contributed to the financial crisis of 2007–2008.

As previously noted, a properly functioning monetary system supports the continuous circular flows of income and expenditures in the economy. In contrast, a malfunctioning monetary system causes major problems in credit markets and can cause severe fluctuations in the economy's levels of output, employment, and prices.

“Malfunctioning” is too gentle an adjective to describe the monetary system in late 2007 and 2008. In that period,

the U.S. financial system faced its most serious crisis since the Great Depression of the 1930s. The financial crisis soon spread to the entire economy, culminating in the severe recession of 2007–2009. We discussed the recession in detail in previous chapters, and we now want to examine the financial crisis that led up to it. What was the nature of the financial crisis? What caused it? How has it changed the structure of the U.S. financial services industry?

The Mortgage Default Crisis

In 2007 a major wave of defaults on home mortgage loans threatened the health of not only the original mortgage lenders but of any financial institution that had made such loans or invested in such loans either directly or indirectly. A majority of these mortgage defaults were on **subprime mortgage loans**—high-interest-rate loans to home buyers with higher-than-average credit risk. Ironically, the federal government had encouraged banks to make these types of loans as part of an effort to broaden home ownership to more Americans. But more directly to the point, several of the biggest indirect investors in these subprime loans had been banks. The banks had lent money to investment companies that had purchased many of the mortgages from mortgage lenders. When the mortgages started to go bad, many investment funds “blew up” and could not repay the loans they had taken out from the banks. The banks thus had to “write off” (declare unrecoverable) the loans they had made to the investment companies, but doing that meant reducing their banks' reserves and limiting their ability to generate new loans. This greatly threatened the economy because both consumers and businesses rely on loans to finance consumption and investment expenditures.

A strange thing about the crisis was that before it happened, banks and government regulators had mistakenly believed that an innovation known as the “mortgage-backed security” had eliminated most of the bank exposure to mortgage defaults. **Mortgage-backed securities** are bonds backed by mortgage payments. To create them, banks and other mortgage lenders first made mortgage loans. But then instead of holding all of those loans as assets on their balance sheets and collecting the monthly mortgage payments, the banks and other mortgage lenders bundled hundreds or thousands of them together and sold them off as bonds—in essence selling the right to collect all the future mortgage payments. The banks obtained a single, up-front cash payment for the bond and the bond buyer started to collect the mortgage payments as the return on the investment.

From the banks' perspective, this seemed like a smart business decision because it transferred any future default risk on those mortgages to the buyer of the bond. The banks thought that they were off the hook for these mortgages. Unfortunately for them, however, they lent a substantial portion of the money they received from selling the bonds to

investment funds that invested in mortgage-backed bonds. They also purchased large amounts of mortgage-backed securities as financial investments to help meet bank capital requirements set by bank regulators. So while the banks were no longer directly exposed to major portions of the mortgage default risk, they were still indirectly exposed to it. When many homebuyers started to default on their mortgages, the banks lost money on the mortgages they still held. The banks also lost money on the loans they had made to the investors who had purchased mortgage-backed securities, and also on the mortgage-backed securities the banks had purchased from investment firms.

But what had caused the skyrocketing mortgage default rates in the first place? There were many causes, including certain government programs that greatly encouraged and subsidized home ownership for former renters. Also contributing were declining real estate values that arrived at the end of a long housing boom during which house prices had greatly increased. But an equally important factor was the bad incentives provided by the previously discussed mortgage-backed bonds. Because the banks and other mortgage lenders thought that they were no longer exposed to large portions of their mortgage default risk, they became lax in their lending practices—so much so that people were granted subprime mortgage loans that they were unlikely to be able to repay. Some mortgage companies were so eager to sign up new homebuyers (in order to bundle their loans together to sell bonds) that they stopped running credit checks and even allowed applicants to claim higher incomes than they were actually earning in order to qualify them for big loans. The natural result was that many people took on “too much mortgage” and were soon failing to make their monthly payments.

Securitization

The problems just described relate to **securitization**—the process of slicing up and bundling groups of loans, mortgages, corporate bonds, or other financial debts into distinct new securities. This process was not new and was viewed favorably by government regulators, who thought securitization made the banking system safer by allowing banks to shed risk. As noted in our discussion of mortgages, these securities were sold to financial investors, who purchased them to obtain the interest payments and the eventual return of principal generated by the underlying securities. For example, the mortgage loans provided to the subprime borrowers were bundled together as mortgage-backed securities and sold to private investors, mutual fund firms, and pension funds. These securities were attractive to many private investors and financial institutions alike because they offered higher-interest returns than securities backed by less-risky mortgages or other safer investments.

Once created, loan-backed securities are bought and sold in financial markets just like other securities such as stocks and bonds. These sorts of securities can therefore end up worldwide in the investment portfolios of banks, thrifts, insurance companies, and pensions, as well as in personal accounts.

To reduce the risk for holders of these securities, a few large insurance companies developed other securities that the holders of loan-backed securities could purchase to insure against losses from defaults. American International Group (AIG), in particular, issued billions of dollars of *collateralized default swaps*—essentially insurance policies—that were designed to compensate the holders of loan-backed securities if the loans underlying these investments went into default and did not pay off. Thus, collateralized default swaps became yet another category of investment security that was highly exposed to mortgage-loan risk.

Securitization is so widespread and so critical to the modern financial system that economists sometimes refer to it as the *shadow banking system*. All sorts of securities backed by loans or other securities are issued, bought, sold, and resold each day in a process that helps to keep credit flowing to the households and firms that rely on it for their personal and business needs. In general, securitization therefore is a positive financial innovation. But mortgage-backed securities, in particular, turned out to contain much more risk than most people thought.

Investors and government regulators failed to ask three related questions about mortgage-backed securities: What would happen if the value of one of the types of loans (say, mortgages) that underlies part of the securitization process unexpectedly plunged? And what then would happen if some of the largest holders of the securities based on these mortgages were major U.S. financial institutions that are vitally important to the day-to-day financing of the credit needed to keep the American economy running smoothly? And what would happen after that if the main insurer of these securities not only was the largest insurance company in the United States but in the world?

All three seemingly improbable “what ifs?” occurred! As previously explained, interest rates on adjustable-rate mortgages increased and house prices fell. Borrowers who had made relatively small down payments on home purchases or had previously cashed out home equity through refinancing discovered that they owed more on their mortgages than their properties were worth. Their loans were said to be “underwater.” As interest rates adjusted upward and the economy slowed, borrowers began falling behind on their monthly mortgage payments. Lenders began to foreclose on many houses, while other borrowers literally handed in their house keys and walked away from their houses *and* their mortgages.

Failures and Near-Failures of Financial Firms

When the mortgage loan “card” underpinning mortgage-based securitization fell, the securitization layers above it collapsed like a house of cards. First, the big mortgage lenders faced demise because they still held large amounts of the bad debt. Three huge mortgage lenders collapsed or nearly collapsed. Countrywide, the second largest mortgage lender, was saved from bankruptcy by Bank of America. Regulators also seized Washington Mutual bank, the nation’s largest mortgage lender, and arranged a quick takeover by JPMorgan Chase. Wachovia bank’s heavy exposure to mortgages through its Golden West subsidiary resulted in near bankruptcy, and it was rescued through acquisition by Wells Fargo.

The exposure to the growing problem of loan defaults quickly jumped from direct mortgage lenders to other financial institutions. Securities firms and investment banks that held large amounts of loan-backed securities began to suffer huge losses. Merrill Lynch lost more in two years than it made in the prior decade and was acquired at a fire-sale price by Bank of America. Lehman Brothers, a major holder of mortgage-backed securities, declared bankruptcy. Goldman Sachs, Morgan Stanley, and other financial firms that had heavy exposures to mortgage-backed securities and collateralized default swaps rushed to become bank holding companies so they could qualify for the massive emergency loans that the Federal Reserve was making available to banks and bank holding companies. Citibank survived through infusions of federal government loans. Insurance company AIG suffered enormous losses because it had not set aside sufficient reserves to pay off the unexpectedly large losses that accrued on the insurance policies that it had sold to holders of mortgage-backed securities. The nightmarish thought of a total collapse of the U.S. financial system suddenly became a realistic possibility.

QUICK REVIEW 34.4

- ✓ The financial crisis of 2007–2008 consisted of an unprecedented rise in mortgage loan defaults, the collapse or near collapse of several major financial institutions, and the generalized freezing up of credit availability.
- ✓ The crisis resulted from bad mortgage loans together with declining real estate prices.
- ✓ The crisis exposed the underestimation of risk by holders of mortgage-backed securities as well as faulty insurance securities that had been designed to protect holders of mortgage-backed securities from the risk of default.

The Policy Response to the Financial Crisis

L034.7 Discuss the actions of the U.S. Treasury and the Federal Reserve that helped keep the banking and financial crisis of 2007–2008 from worsening.

The U.S. government responded to the financial crisis with historically unprecedented fiscal policy actions while the Fed acted aggressively as a lender of last resort.

The Treasury Bailout: TARP

In late 2008, Congress passed the **Troubled Asset Relief Program (TARP)**, which allocated \$700 billion—yes, billion—to the U.S. Treasury to make emergency loans to critical financial and other U.S. firms. Most of this “bailout” money eventually was lent out. In fact, as of March 2009, the federal government and Federal Reserve had spent \$170 billion just keeping insurer AIG afloat. Other major recipients of TARP funds included Citibank, Bank of America, JPMorgan Chase, and Goldman Sachs. Later, nonfinancial firms such as General Motors and Chrysler also received several billion dollars of TARP loans.

TARP indeed saved several financial institutions whose bankruptcy would have caused a tsunami of secondary effects that probably would have brought down other financial firms and frozen credit throughout the economy. But this very fact demonstrates the problem of **moral hazard**. As it relates to financial investment, moral hazard is the tendency for financial investors and financial services firms to take on greater risks because they assume they are at least partially insured against losses. Without TARP, several firms would have gone bankrupt and their stockholders, bondholders, and executives all would have suffered large personal losses. With TARP, those outcomes were at least partially avoided. TARP and similar government bailouts were essentially government-provided insurance payouts to financial firms that never had to pay a single cent in insurance premiums for the massive bailouts that kept them afloat.

The correct assumption by large firms that they were simply too big for government to let them fail may have given them an incentive to make riskier investments than if no government bailouts were likely to be forthcoming.

The Fed’s Lender-of-Last-Resort Activities

As noted in our previous list of Fed functions, one of the roles of the Federal Reserve is to serve as the lender of last resort to financial institutions in times of financial emergencies. The Fed performed this vital function well following the 9/11 terrorist attacks. The financial crisis of 2007–2008 presented another, broader-based financial emergency. Under Fed Chair Ben Bernanke, the Fed designed and implemented several

highly creative new lender-of-last-resort facilities to pump liquidity into the financial system. These facilities, procedures, and capabilities were in addition to both the TARP efforts by the U.S. Treasury and the Fed's use of standard tools of monetary policy (the subject of Chapter 36) designed to reduce interest rates. All the new Fed facilities had the single purpose and desired outcome of keeping credit flowing.

Total Fed assets rose from \$885 billion in February 2008 to \$1,903 billion in March 2009. This increase reflected a huge rise in the amount of securities (U.S. securities, mortgage-backed securities, and others) owned by the Fed. In undertaking its lender-of-last-resort functions, the Fed bought these securities from financial institutions. The purpose was to increase liquidity in the financial system by exchanging illiquid bonds (that the firms could not easily sell during the crisis) for cash, the most liquid of all assets.

Many economists believe that TARP and the Fed's actions helped to avert a second Great Depression. But they also intensified the moral hazard problem by greatly limiting the losses that otherwise would have resulted from bad financial assumptions and decisions. See this chapter's Last Word for more.

QUICK REVIEW 34.5

- ✓ The Troubled Asset Relief Program (TARP) authorized the U.S. Treasury to spend up to \$700 billion to make emergency loans and guarantees to failing financial firms.
- ✓ The Treasury rescue, or bailout, was aided by lender-of-last-resort loans provided by the Federal Reserve to financial institutions through a series of newly established Fed facilities.
- ✓ The TARP loans and the Fed's lender-of-last-resort actions intensified the moral hazard problem in which financial investors and financial firms take on greater risk because they assume that the government will bail them out if they lose money.

The Postcrisis U.S. Financial Services Industry

LO34.8 Identify the main subsets of the financial services industry in the United States and provide examples of some firms in each category.

Table 34.1 lists the major categories of firms within the U.S. financial services industry and gives examples of firms in each category. Note that the main categories of the **financial services industry** are commercial banks, thrifts, insurance companies, mutual fund companies, pension funds, security firms, and investment banks. Even before the financial crisis of 2007–2008, the financial services industry was consolidating

into fewer, larger firms, each offering a wider spectrum of services. In 1999, Congress ended the Depression-era prohibition against banks selling stocks, bonds, and mutual funds. Thus, the lines between the subsets of the financial industry began to blur. Many banks acquired stock brokerage firms and, in a few cases, insurance companies. For example, Citigroup, which was once only into banking, now owns Smith Barney, a large securities firm. Many large banks (for example, Wells Fargo) and pension funds (for example, TIAA-CREF) now provide mutual funds, including money market mutual funds that pay relatively high interest and on which checks of \$500 or more can be written.

The upheaval in the financial markets caused by the financial crisis of 2007–2008 further consolidated the industry and further blurred the lines between its segments. Between September 2007 and September 2009, the FDIC shut down more than 200 U.S. banks and transferred their bank deposits to other, usually larger, banks. In 2009, the three largest U.S. banks (JPMorgan Chase, Bank of America, and Wells Fargo) held roughly \$3 of every \$10 on deposit in the United States.

Also, during the financial crisis of 2007–2008, major investment banks Goldman Sachs and Morgan Stanley opted to become commercial banks to gain access to emergency Federal Reserve loans. The nation's largest thrift—Washington Mutual—was absorbed by commercial bank JPMorgan Chase. But even with all this blending, the categories in Table 34.1 remain helpful. The main lines of a firm's businesses often are in one category or another. For example, even though Goldman Sachs is licensed and regulated as a bank, it is first and foremost an investment company. And the insurance companies and pension funds do most of their business as such.

The financial crisis of 2007–2008 generated much introspection about what went wrong and how to prevent anything like it from happening again. Politicians and financial regulators tightened lending rules to offset the “pass the buck” incentives created by mortgage-backed securities and prevent loans from being issued to people who are unlikely to be able to make the required monthly payments. They also passed legislation to help homeowners who were “underwater” on mortgage loans remain in their homes.

In mid-2010 Congress passed and the president signed the **Wall Street Reform and Consumer Protection Act**. This sweeping law includes provisions that:

- Eliminate the Office of Thrift Supervision and give broader authority to the Federal Reserve to regulate all large financial institutions.
- Create a Financial Stability Oversight Council to be on the lookout for risks to the financial system.
- Establish a process for the federal government to liquidate (sell off) the assets of failing nonbank financial institutions, much like the FDIC does with failing banks.

TABLE 34.1 Major Categories of Financial Institutions within the U.S. Financial Services Industry

Institution	Description	Examples
Commercial banks	State and national banks that provide checking and savings accounts, sell certificates of deposit, and make loans. The Federal Deposit Insurance Corporation (FDIC) insures checking and savings accounts up to \$250,000.	JPMorgan Chase, Bank of America, Citibank, Wells Fargo
Thrifts	Savings and loan associations (S&Ls), mutual saving banks, and credit unions that offer checking and savings accounts and make loans. Historically, S&Ls made mortgage loans for houses while mutual savings banks and credit unions made small personal loans, such as automobile loans. Today, major thrifts offer the same range of banking services as commercial banks. The Federal Deposit Insurance Corporation and the National Credit Union Administration insure checking and savings deposits up to \$250,000.	Charter One, New York Community Bank, Pentagon Federal Credit Union, Boeing Employees Credit Union (BECU)
Insurance companies	Firms that offer policies (contracts) through which individuals pay premiums to insure against some loss, say, disability or death. In some life insurance policies and annuities, the funds are invested for the client in stocks and bonds and paid back after a specified number of years. Thus, insurance sometimes has a saving or financial-investment element.	Prudential, New York Life, Northwestern Mutual, Hartford, MetLife
Mutual fund companies	Firms that pool deposits by customers to purchase stocks or bonds (or both). Customers thus indirectly own a part of a particular set of stocks or bonds, say stocks in companies expected to grow rapidly (a growth fund) or bonds issued by state governments (a municipal bond fund).	Fidelity, Vanguard, Putnam, Janus, T. Rowe Price
Pension funds	For-profit or nonprofit institutions that collect savings from workers (or from employers on their behalf) throughout their working years and then buy stocks and bonds with the proceeds and make monthly retirement payments.	TIAA-CREF, Teamsters' Union, CalPERS
Securities firms	Firms that offer security advice and buy and sell stocks and bonds for clients. More generally known as <i>stock brokerage firms</i> .	Merrill Lynch, TD Ameritrade, Charles Schwab
Investment banks	Firms that help corporations and governments raise money by selling stocks and bonds. They also typically offer advisory services for corporate mergers and acquisitions as well as brokerage services and advice.	Goldman Sachs, Morgan Stanley, Deutsche Bank, Credit Suisse

- Provide federal regulatory oversight of mortgage-backed securities and other derivatives and require that they be traded on public exchanges.
- Require companies selling asset-backed securities to retain a portion of those securities so the sellers share part of the risk.
- Establish a stronger consumer financial protection role for the Fed through creation of the Bureau of Consumer Financial Protection.

Proponents of the new law say that it will help prevent many of the practices that led up to the financial crisis of 2007–2008. They also contend that the law will send a strong message to stockholders, bondholders, and executives of large financial firms that they will suffer unavoidable and extremely high personal financial losses if they allow their firms to ever again get into serious financial trouble.

Skeptics of the new law say that regulators already had all the tools they needed to prevent the financial crisis. They also point out that the government's own efforts to promote home ownership, via quasi-government institutions that purchased mortgage-backed securities, greatly contributed to the financial crisis. Critics of the new law

say that it will simply impose heavy new regulatory costs on the financial industry while doing little to prevent future government bailouts. This chapter's Last Word considers those suspicions.

Extend and Pretend

To Prevent a Total Meltdown During the Financial Crisis of 2007–2008, the Fed Had to Act as a Lender of Last Resort to Both Solvent and Insolvent Firms.

An individual or firm is said to be solvent if the value of its assets exceeds the value of its debts. By contrast, an individual or firm is said to be insolvent if the value of its assets is less than the value of its debts.

A firm that is solvent can be illiquid, meaning that its assets are hard to sell in a hurry. A large factory is a good example. It's hard to find a buyer for a billion-dollar factory quickly. Finding a buyer can take many months or even many years. So a firm whose primary asset is a large factory will be illiquid.

A firm that is solvent but illiquid can be threatened by bankruptcy if it has borrowed money and ends up in a situation in which it can't make timely debt payments. This situation is tricky because if the firm had liquid assets, it could sell those assets quickly to raise the cash that it needs to make timely debt payments. But because its assets are illiquid, the firm will go bankrupt despite being solvent; it won't be able to sell assets fast enough to keep current on its debt obligations.

During a financial crisis, the Fed is supposed to act as a lender of last resort to banks and other financial firms that are solvent but illiquid. The financial firms pledge some of their illiquid assets as collateral in exchange for cash loans issued by the Fed. The firms get the liquidity they need to make timely payments on their loans while the Fed receives collateral that it can sell off later (if necessary) to ensure repayment.

Because the Fed itself is never in a bankruptcy crisis (because it can always print more money to pay off any of its obligations), it can take a leisurely approach to selling off illiquid assets. It is consequently immune to financial crises and thus in a position to lend freely to help calm financial crises.

During a financial crisis, the Fed and other central banks will typically make loans to insolvent firms as well as solvent firms. The insolvent firms also have to pledge assets to obtain loans from the Fed, but the fact that they are insolvent means that they are not capable of paying back all of their creditors—including the Fed, now that it has lent them money.

So why would the Fed put itself in that situation? Why would the Fed extend loans to firms that may lack the financial resources to pay the Fed back?

The answer is that during a financial crisis the Fed is worried that if it does not extend credit to insolvent firms, the insolvent firms

will go bankrupt and cease to make timely debt payments to solvent firms, something that could then drive the solvent firms into bankruptcy, too.

The Fed is consequently under pressure during major a financial crisis to extend emergency loans to *any* firm that can post assets as collateral. By not discriminating between solvent and insolvent firms, the Fed is in essence pretending that all firms are just in need of a little liquidity to get them through the crisis. The hope is that once the crisis is over, the insolvent firms will be able to either go quietly into bankruptcy or find another company that is willing to buy them or invest in them (for a low enough price).

During the financial crisis of 2007–2008, the Fed extended loans to both solvent and insolvent firms. This policy of “extend and pretend” was both widely praised and widely criticized. On the one hand, the Fed prevented the financial meltdown that would have occurred if the bankruptcies of insolvent firms had also taken down solvent firms. On the other hand, many poorly managed firms that had become insolvent due to making bad investments avoided well-deserved bankruptcies. Not only was this unfair to well-managed firms, it increased moral hazard going forward. Banks and other financial companies will be more likely to engage in risky behavior because they will expect both solvent and insolvent firms to have equal access to emergency loans when the next crisis hits.

SUMMARY

LO34.1 Identify and explain the functions of money.

Anything that is accepted as (a) a medium of exchange, (b) a unit of monetary account, and (c) a store of value can be used as money.

LO34.2 List and describe the components of the U.S. money supply.

There are two major definitions of the money supply. *M1* consists of currency and checkable deposits; *M2* consists of *M1* plus savings deposits, including money market deposit accounts, small-denominated (less than \$100,000) time deposits, and money market mutual fund balances held by individuals.

LO34.3 Describe what “backs” the money supply, making us willing to accept it as payment.

Money represents the debts of government and institutions offering checkable deposits (commercial banks and thrift institutions) and has value because of the goods, services, and resources it will command in the market. Maintaining the purchasing power of money depends largely on the government’s effectiveness in managing the money supply.

LO34.4 Discuss the makeup of the Federal Reserve and its relationship to banks and thrifts.

The U.S. banking system consists of (a) the Board of Governors of the Federal Reserve System, (b) the 12 Federal Reserve Banks, and (c) some 6,000 commercial banks and 8,500 thrift institutions (mainly credit unions). The Board of Governors is the basic policymaking body for the entire banking system. The directives of the Board and the Federal Open Market Committee (FOMC) are made effective through the 12 Federal Reserve Banks, which are simultaneously (a) central banks, (b) quasi-public banks, and (c) bankers’ banks.

LO34.5 Identify the functions and responsibilities of the Federal Reserve and explain why Fed independence is important.

The major functions of the Fed are to (a) issue Federal Reserve Notes, (b) set reserve requirements and hold reserves deposited by banks and thrifts, (c) lend money to financial institutions and serve as the lender of last resort in national financial emergencies, (d) provide for the rapid collection of checks, (e) act as the fiscal agent for the federal government, (f) supervise the operations of the banks, and (g) regulate the supply of money in the best interests of the economy.

The Fed is essentially an independent institution, controlled neither by the president of the United States nor by Congress. This independence shields the Fed from political pressure and allows it to raise and lower interest rates (via changes in the money supply) as needed to promote full employment, price stability, and economic growth.

LO34.6 Identify and explain the main factors that contributed to the financial crisis of 2007–2008.

The financial crisis of 2007–2008 consisted of an unprecedented rise in mortgage loan defaults, the collapse or near-collapse of several major financial institutions, and the generalized freezing up of credit availability. The crisis resulted from bad mortgage loans together with declining real estate prices. It also resulted from underestimation of risk by holders of mortgage-backed securities and faulty insurance securities designed to protect holders of mortgage-backed securities from the risk of default.

LO34.7 Discuss the actions of the U.S. Treasury and the Federal Reserve that helped keep the banking and financial crisis of 2007–2008 from worsening.

In 2008 Congress passed the Troubled Asset Relief Program (TARP), which authorized the U.S. Treasury to spend up to \$700 billion to make emergency loans and guarantees to failing financial firms. The Treasury rescue, or bailout, was aided by lender-of-last-resort loans provided by the Federal Reserve to financial institutions through a series of newly established Fed facilities.

The TARP loans and the Fed’s lender-of-last-resort actions intensify the moral hazard problem. This is the tendency of financial investors and financial firms to take on greater risk when they assume they are at least partially insured against loss.

LO34.8 Identify the main subsets of the financial services industry in the United States and provide examples of some firms in each category.

The main categories of the U.S. financial services industry are commercial banks, thrifts, insurance companies, mutual fund companies, pension funds, securities firms, and investment banks. The reassembly of the wreckage from the financial crisis of 2007–2008 has further consolidated the already-consolidating financial services industry and has further blurred some of the lines between the subsets of the industry.

In response to the financial crisis, Congress passed the Wall Street Reform and Consumer Financial Protection Act of 2010.

DISCUSSION QUESTIONS

- What are the three basic functions of money? Describe how rapid inflation can undermine money's ability to perform each of the three functions. **L034.1**
- Which two of the following financial institutions offer checkable deposits included within the *M1* money supply: mutual fund companies; insurance companies; commercial banks; securities firms; thrift institutions? Which of the following items is *not* included in either *M1* or *M2*: currency held by the public; checkable deposits; money market mutual fund balances; small-denominated (less than \$100,000) time deposits; currency held by banks; savings deposits? **L034.2**
- What are the components of the *M1* money supply? What is the largest component? Which of the components of *M1* is legal tender? Why is the face value of a coin greater than its intrinsic value? What near-monies are included in the *M2* money supply? **L034.2**
- Explain and evaluate the following statements: **L034.2**
 - The invention of money is one of the great achievements of humankind, for without it the enrichment that comes from broadening trade would have been impossible.
 - Money is whatever society says it is.
 - In the United States, the debts of government and commercial banks are used as money.
 - People often say they would like to have more money, but what they usually mean is that they would like to have more goods and services.
 - When the price of everything goes up, it is not because everything is worth more but because the currency is worth less.
 - Any central bank can create money; the trick is to create enough, but not too much, of it.
- What "backs" the money supply in the United States? What determines the value (domestic purchasing power) of money? How does the purchasing power of money relate to the price level? Who in the United States is responsible for maintaining money's purchasing power? **L034.3**
- How is the chairperson of the Federal Reserve System selected? Describe the relationship between the Board of Governors of the Federal Reserve System and the 12 Federal Reserve Banks. What is the purpose of the Federal Open Market Committee (FOMC)? What is its makeup? **L034.4**
- The following are two hypothetical ways in which the Federal Reserve Board might be appointed. Would you favor either of these two methods over the present method? Why or why not? **L034.4**
 - Upon taking office, the U.S. president appoints seven people to the Federal Reserve Board, including a chair. Each appointee must be confirmed by a majority vote of the Senate, and each serves the same 4-year term as the president.
 - Congress selects seven members from its ranks (four from the House of Representatives and three from the Senate) to serve at congressional pleasure as the Board of Governors of the Federal Reserve System.
- What is meant when economists say that the Federal Reserve Banks are central banks, quasi-public banks, and bankers' banks? **L034.4**
- Why do economists nearly uniformly support an independent Fed rather than one beholden directly to either the president or Congress? **L034.5**
- Identify three functions of the Federal Reserve of your choice, other than its main role of controlling the supply of money. **L034.5**
- How does each of the following relate to the financial crisis of 2007–2008: declines in real estate values, subprime mortgage loans, mortgage-backed securities, AIG. **L034.6**
- What is TARP and how was it funded? What is meant by the term "lender of last resort" and how does it relate to the financial crisis of 2007–2008? How do government and Federal Reserve emergency loans relate to the concept of moral hazard? **L034.7**
- What are the major categories of firms that make up the U.S. financial services industry? Are there more or fewer banks today than before the start of the financial crisis of 2007–2008? Why are the lines between the categories of financial firms even more blurred than they were before the crisis? How did the Wall Street Reform and Consumer Protection Act of 2010 try to address some of the problems that helped cause the crisis? **L034.8**
- LAST WORD** A firm enters bankruptcy when it misses a debt payment. So does being insolvent imply being bankrupt? Explain. And why is the Fed reluctant to distinguish between solvent and insolvent firms during a financial crisis?

- L035.4** Describe the multiple expansion of loans and money by the entire banking system.
- L035.5** Define the monetary multiplier, explain how to calculate it, and demonstrate its relevance.

We have seen that the $M1$ money supply consists of currency (coins and Federal Reserve Notes) and checkable deposits and that $M1$ is a base component of $M2$, a broader measure of the money supply that also includes savings deposits, small-denominated time deposits, and balances in money market mutual funds. The U.S. Mint produces the coins and the U.S. Bureau of Engraving and Printing creates the Federal Reserve Notes. So who creates the checkable deposits? Surprisingly, it is loan officers! Although that may sound like something a congressional committee

should investigate, the monetary authorities are well aware that banks and thrifts create checkable deposits. In fact, the Federal Reserve relies on these institutions to create this vital component of the nation’s money supply.

The Fractional Reserve System

L035.1 Discuss why the U.S. banking system is called a “fractional reserve” system.

The United States, like most other countries today, has a **fractional reserve banking system** in which only a portion (fraction) of checkable deposits are backed up by reserves of currency in bank vaults or deposits at the central bank. Our goal is to explain this system and show how commercial banks can create checkable deposits by issuing loans. Our examples will involve commercial banks, but remember that thrift institutions also provide checkable deposits. So the analysis applies to banks and thrifts alike.

Illustrating the Idea: The Goldsmiths

Here is the history behind the idea of the fractional reserve system.

When early traders began to use gold in making transactions, they soon realized that it was both unsafe and inconvenient to carry gold and to have it weighed and assayed (judged for purity) every time they negotiated a transaction. So by the sixteenth century they had begun to deposit their gold with

goldsmiths, who would store it in vaults for a fee. On receiving a gold deposit, the goldsmith would issue a receipt to the depositor. Soon people were paying for goods with goldsmiths' receipts, which served as one of the first types of paper money.

At this point the goldsmiths—embryonic bankers—used a 100 percent reserve system; they backed their circulating paper money receipts fully with the gold that they held “in reserve” in their vaults. But because of the public's acceptance of the goldsmiths' receipts as paper money, the goldsmiths soon realized that owners rarely redeemed the gold they had in storage. In fact, the goldsmiths observed that the amount of gold being deposited with them in any week or month was likely to exceed the amount that was being withdrawn.

Then some clever goldsmith hit on the idea that paper “receipts” could be issued in excess of the amount of gold held. Goldsmiths would put these receipts, which were redeemable in gold, into circulation by making interest-earning loans to merchants, producers, and consumers. A borrower might, for instance, borrow \$10,000 worth of gold receipts today with the promise to repay \$10,500 worth of gold receipts in one year (a 5 percent interest rate). Borrowers were willing to accept loans in the form of gold receipts because the receipts were accepted as a medium of exchange in the marketplace.

This was the beginning of the fractional reserve system of banking, in which reserves in bank vaults are a fraction of the total money supply. If, for example, the goldsmith issued \$1 million in receipts for actual gold in storage and another \$1 million in receipts as loans, then the total value of paper money in circulation would be \$2 million—twice the value of the gold. Gold reserves would be a fraction (one-half) of outstanding paper money.

Significant Characteristics of Fractional Reserve Banking

The goldsmith story highlights two significant characteristics of fractional reserve banking. First, banks can create money through lending. In fact, goldsmiths created money when they made loans by giving borrowers paper money that was not fully backed by gold reserves. The quantity of such money goldsmiths could create depended on the amount of reserves they deemed prudent to have available. The smaller the amount of reserves thought necessary, the larger the amount of paper money the goldsmiths could create. Today, gold is no longer used as bank reserves. Instead, currency itself serves as bank reserves so that the creation of checkable-deposit money by banks (via their lending) is limited by the amount of *currency reserves* that the banks feel obligated, or are required by law, to keep.

A second reality is that banks operating on the basis of fractional reserves are vulnerable to “panics” or “runs.” A goldsmith who issued paper money equal to twice the value of his gold reserves would be unable to convert all that paper money into gold in the event that all the holders of that money

appeared at his door at the same time demanding their gold. In fact, many European and U.S. banks were once ruined by this unfortunate circumstance. However, a bank panic is highly unlikely if the banker's reserve and lending policies are prudent. Indeed, one reason why banking systems are highly regulated industries is to prevent runs on banks.

This is also why the United States has the system of deposit insurance that we discussed in the last chapter. By guaranteeing deposits, deposit insurance helps to prevent the sort of bank runs that used to happen so often before deposit insurance was available. In those situations, rumors would spread that a bank was about to go bankrupt and that it only had a small amount of reserves left in its vaults. Bank runs are called “bank runs” because depositors would run to the bank trying to be one of the lucky few to withdraw their money while the bank had any reserves left. The rumors were usually totally unfounded. But, unfortunately, the bank would still go bankrupt even if it began the day with its normal amount of reserves. With so many customers withdrawing money simultaneously, it would run out of reserves and be forced to default on its obligations to its remaining depositors. By guaranteeing depositors that they will always get their money, deposit insurance removes the incentive to try to withdraw one's deposit before anyone else can. It thus stops most bank runs.

A Single Commercial Bank

L035.2 Explain the basics of a bank's balance sheet and the distinction between a bank's actual reserves and its required reserves.

To illustrate the workings of the modern fractional reserve banking system, we need to examine a commercial bank's balance sheet.

The **balance sheet** of a commercial bank (or thrift) is a statement of assets—things owned by the bank or owed to the bank—and claims on those assets. A bank balance sheet summarizes the financial position of the bank at a certain time. Every balance sheet must balance; this means that the value of *assets* must equal the amount of claims against those assets. The claims shown on a balance sheet are divided into two groups: the claims of nonowners of the bank against the firm's assets, called *liabilities*, and the claims of the owners of the firm against the firm's assets, called *net worth*. Liabilities are things owed by the bank to depositors or others. A balance sheet is balanced because

$$\text{Assets} = \text{liabilities} + \text{net worth}$$

Every \$1 change in assets must be offset by a \$1 change in liabilities + net worth. Every \$1 change in liabilities + net worth must be offset by a \$1 change in assets.

Now let's work through a series of bank transactions involving balance sheets to establish how individual banks can create money.

Transaction 1: Creating a Bank

Suppose some far-sighted citizens of the town of Wahoo, Nebraska (yes, there is such a place), decide their town needs a new commercial bank to provide banking services for that growing community. Once they have secured a state or national charter for their bank, they turn to the task of selling, say, \$250,000 worth of stock (equity shares) to buyers, both in and out of the community. Their efforts meet with success and the Bank of Wahoo comes into existence—at least on paper. What does its balance sheet look like at this stage?

The founders of the bank have sold \$250,000 worth of shares of stock in the bank—some to themselves, some to other people. As a result, the bank now has \$250,000 in cash on hand and \$250,000 worth of stock shares outstanding. The cash is an asset to the bank. Cash held by a bank is sometimes called **vault cash** or till money. The shares of stock outstanding constitute an equal amount of claims that the owners have against the bank's assets. Those shares of stock constitute the net worth of the bank. The bank's balance sheet reads:

Creating a Bank Balance Sheet 1: Wahoo Bank			
Assets		Liabilities and net worth	
Cash	\$250,000	Stock shares	\$250,000

Each item listed in a balance sheet such as this is called an *account*.

Transaction 2: Acquiring Property and Equipment

The board of directors (who represent the bank's owners) must now get the new bank off the drawing board and make it a reality. First, property and equipment must be acquired. Suppose the directors, confident of the success of their venture, purchase a building for \$220,000 and pay \$20,000 for office equipment. This simple transaction changes the composition of the bank's assets. The bank now has \$240,000 less in cash and \$240,000 of new property assets. Using blue to denote accounts affected by each transaction, we find that the bank's balance sheet at the end of transaction 2 appears as follows:

Acquiring Property and Equipment Balance Sheet 2: Wahoo Bank			
Assets		Liabilities and net worth	
Cash	\$ 10,000	Stock shares	\$250,000
Property	240,000		

Note that the balance sheet still balances, as it must.

Transaction 3: Accepting Deposits

Commercial banks have two basic functions: to accept deposits of money and to make loans. Now that the bank is operating, suppose that the citizens and businesses of Wahoo decide to deposit \$100,000 in the Wahoo bank. What happens to the bank's balance sheet?

The bank receives cash, which is an asset to the bank. Suppose this money is deposited in the bank as checkable deposits (checking account entries), rather than as savings accounts or time deposits. These newly created *checkable deposits* constitute claims that the depositors have against the assets of the Wahoo bank and thus are a new liability account. The bank's balance sheet now looks like this:

Accepting Deposits Balance Sheet 3: Wahoo Bank			
Assets		Liabilities and net worth	
Cash	\$110,000	Checkable deposits	\$100,000
Property	240,000	Stock shares	250,000

There has been no change in the economy's total supply of money as a result of transaction 3, but a change has occurred in the composition of the money supply. Bank money, or checkable deposits, has increased by \$100,000, and currency held by the public has decreased by \$100,000. As explained in the previous chapter, currency held in a bank is not part of the economy's money supply.

A withdrawal of cash will reduce the bank's checkable-deposit liabilities and its holdings of cash by the amount of the withdrawal. This, too, changes the composition, but not the total supply, of money in the economy.

Transaction 4: Depositing Reserves in a Federal Reserve Bank

All commercial banks and thrift institutions that provide checkable deposits must by law keep **required reserves**. Required reserves are an amount of funds equal to a specified percentage of the bank's own deposit liabilities. A bank must keep these reserves on deposit with the Federal Reserve Bank in its district or as cash in the bank's vault. To simplify, we suppose the Bank of Wahoo keeps its required reserves entirely as deposits in the Federal Reserve Bank of its district. But remember that vault cash is counted as reserves and real-world banks keep a significant portion of their own reserves in their vaults.

The "specified percentage" of checkable-deposit liabilities that a commercial bank must keep as reserves is known as the **reserve ratio**—the ratio of the required reserves the

commercial bank must keep to the bank's own outstanding checkable-deposit liabilities:

$$\text{Reserve ratio} = \frac{\text{commercial bank's required reserves}}{\text{commercial bank's checkable-deposit liabilities}}$$

If the reserve ratio is $\frac{1}{10}$, or 10 percent, the Wahoo bank, having accepted \$100,000 in deposits from the public, would have to keep \$10,000 as reserves. If the ratio is $\frac{1}{5}$, or 20 percent, \$20,000 of reserves would be required. If $\frac{1}{2}$, or 50 percent, \$50,000 would be required.

The Fed has the authority to establish and vary the reserve ratio within limits legislated by Congress. The limits now prevailing are shown in Table 35.1. The first \$15.2 million of checkable deposits held by a commercial bank or thrift is exempt from reserve requirements. A 3 percent reserve is required on checkable deposits of between \$15.2 million and \$110.2 million. A 10 percent reserve is required on checkable deposits over \$110.2 million, although the Fed can vary that percentage between 8 and 14 percent. Currently, no reserves are required against noncheckable nonpersonal (business) savings or time deposits, although up to 9 percent can be required. Also, after consultation with appropriate Congressional committees, the Fed for 180 days may impose reserve requirements outside the 8 to 14 percent range specified in Table 35.1. Beginning in late 2008, the Fed began paying banks interest on both required reserves as well as excess reserves held at Federal Reserve Banks.

In order to simplify, we will suppose that the reserve ratio for checkable deposits in commercial banks is $\frac{1}{5}$ or 20 percent. Although 20 percent obviously is higher than the requirement really is, the figure is convenient for calculations. Because we are concerned only with checkable (spendable) deposits, we ignore reserves on noncheckable savings and time deposits. The main point is that reserve requirements are fractional, meaning that they are less than 100 percent. This point is critical in our analysis of the lending ability of the banking system.

TABLE 35.1 Reserve Requirements (Reserve Ratios) for Banks and Thrifts, 2016

Type of Deposit	Current Requirement	Statutory Limits
Checkable deposits:		
\$0–\$15.2 million	0%	3%
\$15.2–\$110.2 million	3	3
Over \$110.2 million	10	8–14
Noncheckable nonpersonal savings and time deposits	0	0–9

By depositing \$20,000 in the Federal Reserve Bank, the Wahoo bank will just be meeting the required 20 percent ratio between its reserves and its own deposit liabilities. We will use “reserves” to mean the funds commercial banks deposit in the Federal Reserve Banks to distinguish those funds from the public's deposits in commercial banks.

But suppose the Wahoo bank anticipates that its holdings of checkable deposits will grow in the future. Then, instead of sending just the minimum amount, \$20,000, it sends an extra \$90,000, for a total of \$110,000. In so doing, the bank will avoid the inconvenience of sending additional reserves to the Federal Reserve Bank each time its own checkable-deposit liabilities increase. And, as you will see, it is these extra reserves that enable banks to lend money and earn interest income.

Actually, a real-world bank would not deposit *all* its cash in the Federal Reserve Bank. However, because (1) banks as a rule hold vault cash only in the amount of $1\frac{1}{2}$ or 2 percent of their total assets and (2) vault cash can be counted as reserves, we will assume for simplicity that all of Wahoo's cash is deposited in the Federal Reserve Bank and therefore constitutes the commercial bank's actual reserves. By making this simplifying assumption, we do not need to bother adding two assets—“cash” and “deposits in the Federal Reserve Bank”—to determine “reserves.”

After the Wahoo bank deposits \$110,000 of reserves at the Fed, its balance sheet becomes:

Assets		Liabilities and net worth	
Cash	\$ 0	Checkable deposits	\$110,000
Reserves	110,000	Stock shares	250,000
Property	240,000		

There are three things to note about this latest transaction.

Excess Reserves A bank's **excess reserves** are found by subtracting its *required reserves* from its **actual reserves**:

$$\text{Excess reserves} = \text{actual reserves} - \text{required reserves}$$

In this case,

Actual reserves	\$110,000
Required reserves	<u>–20,000</u>
Excess reserves	\$ 90,000

The only reliable way of computing excess reserves is to multiply the bank's checkable-deposit liabilities by the reserve ratio to obtain required reserves (\$100,000 \times 20 percent = \$20,000) and then to subtract the required reserves from the actual reserves listed on the asset side of the bank's balance sheet.

To test your understanding, compute the bank's excess reserves from Balance Sheet 4, assuming that the reserve ratio is (1) 10 percent, (2) $33\frac{1}{3}$ percent, and (3) 50 percent.

We will soon demonstrate that the ability of a commercial bank to make loans depends on the existence of excess reserves. Understanding this concept is crucial in seeing how the banking system creates money.

Control You might think the basic purpose of reserves is to enhance the liquidity of a bank and protect commercial bank depositors from losses. Reserves would constitute a ready source of funds from which commercial banks could meet large, unexpected cash withdrawals by depositors.

But this reasoning breaks down under scrutiny. Although historically reserves have been seen as a source of liquidity and therefore as protection for depositors, a bank's required reserves are not great enough to meet sudden, massive cash withdrawals. If the banker's nightmare should materialize—everyone with checkable deposits appearing at once to demand those deposits in cash—the actual reserves held as vault cash or at the Federal Reserve Bank would be insufficient. The banker simply could not meet this “bank panic.” Because reserves are fractional, checkable deposits may be much greater than a bank's required reserves.

So commercial bank deposits must be protected by other means. Periodic bank examinations are one way of promoting prudent commercial banking practices. Furthermore, insurance funds administered by the Federal Deposit Insurance Corporation (FDIC) and the National Credit Union Administration (NCUA) insure individual deposits in banks and thrifts up to \$250,000.

If it is not the purpose of reserves to provide for commercial bank liquidity, then what is their function? *Control* is the answer. Required reserves help the Fed control the lending ability of commercial banks. The Fed can take certain actions that either increase or decrease commercial bank reserves and affect the ability of banks to grant credit. The objective is to prevent banks from overextending or underextending bank credit. To the degree that these policies successfully influence the volume of commercial bank credit, the Fed can help the economy avoid business fluctuations. Another function of reserves is to facilitate the collection or “clearing” of checks.

Asset and Liability Transaction 4 brings up another matter. Specifically, the reserves created in transaction 4 are an asset to the depositing commercial bank because they are a claim this bank has against the assets of another institution—the Federal Reserve Bank. The checkable deposit you get by depositing money in a commercial bank is an asset to you and a liability to the bank (since the bank is liable for repaying you whenever you choose to withdraw your deposit). In the same way, the reserves that a commercial bank establishes by

depositing money in a bankers' bank are an asset to the commercial bank and a liability to the Federal Reserve Bank.

Transaction 5: Clearing a Check Drawn against the Bank

Assume that Fred Bradshaw, a Wahoo farmer, deposited a substantial portion of the \$100,000 in checkable deposits that the Wahoo bank received in transaction 3. Now suppose that Fred buys \$50,000 of farm machinery from the Ajax Farm Implement Company of Surprise, Nebraska. Bradshaw pays for this machinery by writing a \$50,000 check against his deposit in the Wahoo bank. He gives the check to the Ajax Company. What are the results?

Ajax deposits the check in its account with the Surprise bank. The Surprise bank increases Ajax's checkable deposits by \$50,000 when Ajax deposits the check. Ajax is now paid in full. Bradshaw is pleased with his new machinery.

Now the Surprise bank has Bradshaw's check. This check is simply a claim against the assets of the Wahoo bank. The Surprise bank will collect this claim by sending the check (along with checks drawn on other banks) to the regional Federal Reserve Bank. Here a bank employee will clear, or collect, the check for the Surprise bank by increasing Surprise's reserve in the Federal Reserve Bank by \$50,000 and decreasing the Wahoo bank's reserve by that same amount. The check is “collected” merely by making bookkeeping notations to the effect that Wahoo's claim against the Federal Reserve Bank is reduced by \$50,000 and Surprise's claim is increased by \$50,000.

Finally, the Federal Reserve Bank sends the cleared check back to the Wahoo bank, and for the first time the Wahoo bank discovers that one of its depositors has drawn a check for \$50,000 against his checkable deposit. Accordingly, the Wahoo bank reduces Bradshaw's checkable deposit by \$50,000 and notes that the collection of this check has caused a \$50,000 decline in its reserves at the Federal Reserve Bank. All the balance sheets balance: The Wahoo bank has reduced both its assets (reserves) and its liabilities (checkable deposits) by \$50,000. The Surprise bank has \$50,000 more in both assets (reserves) and liabilities (checkable deposits). Ownership of reserves at the Federal Reserve Bank has changed—with Wahoo owning \$50,000 less and Surprise owning \$50,000 more—but total reserves stay the same.

Whenever a check is drawn against one bank and deposited in another bank, collection of that check will reduce both the reserves and the checkable deposits of the bank on which the check is drawn. Conversely, if a bank receives a check drawn on another bank, the bank receiving the check will, in the process of collecting it, have its reserves and deposits increased by the amount of the check. In our example, the Wahoo bank loses \$50,000 in both reserves and deposits to the Surprise bank. But there is no loss of reserves or deposits

for the banking system as a whole. What one bank loses, another bank gains.

If we bring all the other assets and liabilities back into the picture, the Wahoo bank's balance sheet looks like this at the end of transaction 5:

Clearing a Check Balance Sheet 5: Wahoo Bank			
Assets		Liabilities and net worth	
Reserves	\$ 60,000	Checkable deposits	\$ 50,000
Property	240,000	Stock shares	250,000

Verify that with a 20 percent reserve requirement, the bank's excess reserves now stand at \$50,000.

QUICK REVIEW 35.1

- ✓ The United States has a fractional reserve banking system, in which the collective reserves of the banks usually are considerably less than 100 percent of their checkable deposit liabilities.
- ✓ When a bank accepts deposits of cash, the composition of the money supply is changed, but the total supply of money is not directly altered.
- ✓ Commercial banks and thrifts are obliged to keep required reserves equal to a specified percentage of their own checkable-deposit liabilities as cash or on deposit with the Federal Reserve Bank of their district.
- ✓ The amount by which a bank's actual reserves exceed its required reserves is called excess reserves.
- ✓ A bank that has a check drawn and collected against it will lose to the recipient bank both reserves and deposits equal to the value of the check.

Money-Creating Transactions of a Commercial Bank

LO35.3 Describe how a bank can create money.

The next two transactions are crucial because they explain (1) how a commercial bank can literally create money by making loans and (2) how banks create money by purchasing government bonds from the public.

Transaction 6: Granting a Loan

In addition to accepting deposits, commercial banks grant loans to borrowers. What effect does lending by a commercial bank have on its balance sheet?

Suppose the Gristly Meat Packing Company of Wahoo decides it is time to expand its facilities. Suppose, too, that the company needs exactly \$50,000—which just happens to

be equal to the Wahoo bank's excess reserves—to finance this project.

Gristly goes to the Wahoo bank and requests a loan for this amount. The Wahoo bank knows the Gristly Company's fine reputation and financial soundness and is convinced of its ability to repay the loan. So the loan is granted. In return, the president of Gristly hands a promissory note—a fancy IOU—to the Wahoo bank. Gristly wants the convenience and safety of paying its obligations by check. So, instead of receiving a basket full of currency from the bank, Gristly gets a \$50,000 increase in its checkable-deposit account in the Wahoo bank.

The Wahoo bank has acquired an interest-earning asset (the promissory note, which it files under “Loans”) and has created checkable deposits (a liability) to “pay” for this asset. Gristly has swapped an IOU for the right to draw an additional \$50,000 worth of checks against its checkable deposit in the Wahoo bank. Both parties are pleased.

At the moment the loan is completed, the Wahoo bank's position is shown by Balance Sheet 6a:

When a Loan Is Negotiated Balance Sheet 6a: Wahoo Bank			
Assets		Liabilities and net worth	
Reserves	\$ 60,000	Checkable deposits	\$100,000
Loans	50,000	Stock shares	250,000
Property	240,000		

All this looks simple enough. But a close examination of the Wahoo bank's balance statement reveals a startling fact: When a bank makes loans, it creates money. The president of Gristly went to the bank with something that is *not* money—her IOU—and walked out with something that *is* money—a checkable deposit.

Contrast Balance Sheet 6a with transaction 3, in which checkable deposits were created but only as a result of currency having been taken out of circulation. There was a change in the *composition* of the money supply in that situation but no change in the *total supply* of money. But when banks lend, they create checkable deposits that *are* money. By extending credit, the Wahoo bank has “monetized” an IOU. Gristly and the Wahoo bank have created and then swapped claims. The claim created by Gristly and given to the bank is not money; an individual's IOU is not acceptable as a medium of exchange. But the claim created by the bank and given to Gristly *is* money; checks drawn against a checkable deposit are acceptable as a medium of exchange. Checkable-deposit money like this constitutes about one-half the quantity of *M1* money in the United States and about 10 percent of *M2*.

Much of the money used in the United States therefore is created through the extension of credit by commercial banks. This checkable-deposit money may be thought of as “debts” of commercial banks and thrift institutions. Checkable deposits

are bank debts in the sense that they are claims that banks and thrifts promise to pay “on demand.”

But certain factors limit the ability of a commercial bank to create checkable deposits (“bank money”) by lending. The Wahoo bank can expect the newly created checkable deposit of \$50,000 to be a very active account. Gristly would not borrow \$50,000 at, say, 7, 10, or 12 percent interest for the sheer joy of knowing that funds were available if needed.

Assume that Gristly awards a \$50,000 building contract to the Quickbuck Construction Company of Omaha. Quickbuck, true to its name, completes the expansion promptly and is paid with a check for \$50,000 drawn by Gristly against its checkable deposit in the Wahoo bank. Quickbuck, with headquarters in Omaha, does not deposit this check in the Wahoo bank but instead deposits it in the Fourth National Bank of Omaha. Fourth National now has a \$50,000 claim against the Wahoo bank. The check is collected in the manner described in Balance Sheet 5. As a result, the Wahoo bank loses both reserves and deposits equal to the amount of the check; Fourth National acquires \$50,000 of reserves and deposits.

In summary, assuming a check is drawn by the borrower for the entire amount of the loan (\$50,000) and is given to a firm that deposits it in some other bank, the Wahoo bank’s balance sheet will read as follows after the check has been cleared against it:

After a Check Is Drawn on the Loan Balance Sheet 6b: Wahoo Bank			
Assets		Liabilities and net worth	
Reserves	\$ 10,000	Checkable deposits	\$ 50,000
Loans	50,000		
Property	240,000	Stock shares	250,000

After the check has been collected, the Wahoo bank just meets the required reserve ratio of 20 percent (= \$10,000/\$50,000). The bank has *no* excess reserves. This poses a question: Could the Wahoo bank have lent more than \$50,000—an amount greater than its excess reserves—and still have met the 20 percent reserve requirement when a check for the full amount of the loan was cleared against it? The answer is no; the bank is “fully loaned up.”

Here is why: Suppose the Wahoo bank had lent \$55,000 to the Gristly company and that the Gristly company had spent all of that money by writing a \$55,000 check to Quickbuck Construction. Collection of the check against the Wahoo bank would have lowered its reserves to \$5,000 (= \$60,000 – \$55,000), and checkable deposits would once again stand at \$50,000 (= \$105,000 – \$55,000). The ratio of actual reserves to checkable deposits would then be \$5,000/\$50,000, or only 10 percent. Because the reserve requirement is 20 percent, the Wahoo bank could not have lent \$55,000.

By experimenting with other amounts over \$50,000, you will find that the maximum amount the Wahoo bank could

lend at the outset of Balance Sheet 6 is \$50,000. This amount is identical to the amount of excess reserves the bank had available when the loan was negotiated.

A single commercial bank in a multibank banking system can lend only an amount equal to its initial preloan excess reserves. When it lends, the lending bank faces the possibility that checks for the entire amount of the loan will be drawn and cleared against it. If that happens, it will lose (to other banks) reserves equal to the amount it lends. So, to be safe, it limits its lending to the amount of its excess reserves.

Bank creation of money raises an interesting question: If a bank creates checkable-deposit money when it lends its excess reserves, is money destroyed when borrowers pay off loans? The answer is yes. When loans are paid off, the process works in reverse. The bank’s checkable deposits decline by the amount of the loan repayment.

Transaction 7: Buying Government Securities

When a commercial bank buys government bonds from the public, the effect is substantially the same as lending. New money is created.

Assume that the Wahoo bank’s balance sheet initially stands as it did at the end of transaction 5. Now suppose that instead of making a \$50,000 loan, the bank buys \$50,000 of government securities from a securities dealer. The bank receives the interest-bearing bonds, which appear on its balance statement as the asset “Securities,” and gives the dealer an increase in its checkable-deposit account. The Wahoo bank’s balance sheet appears as follows:

Buying Government Securities Balance Sheet 7: Wahoo Bank			
Assets		Liabilities and net worth	
Reserves	\$ 60,000	Checkable deposits	\$100,000
Securities	50,000		
Property	240,000	Stock shares	250,000

Checkable deposits, that is, the supply of money, have been increased by \$50,000, as in Balance Sheet 6. Bond purchases from the public by commercial banks increase the supply of money in the same way as lending to the public does. The bank accepts government bonds (which are not money) and gives the securities dealer an increase in its checkable deposits (which *are* money).

Of course, when the securities dealer draws and clears a check for \$50,000 against the Wahoo bank, the bank loses both reserves and deposits in that amount and then just meets the legal reserve requirement. Its balance sheet now reads precisely as in Balance Sheet 6b except that “Securities” is substituted for “Loans” on the asset side.

Finally, the *selling* of government bonds to the public by a commercial bank—like the repayment of a loan—reduces

the supply of money. The securities buyer pays by check, and both “Securities” and “Checkable deposits” (the latter being money) decline by the amount of the sale.

Profits, Liquidity, and the Federal Funds Market

The asset items on a commercial bank’s balance sheet reflect the banker’s pursuit of two conflicting goals:

- **Profit** One goal is profit. Commercial banks, like any other businesses, seek profits, which is why the bank makes loans and buys securities—the two major earning assets of commercial banks.
- **Liquidity** The other goal is safety. For a bank, safety lies in liquidity, specifically such liquid assets as cash and excess reserves. A bank must be on guard for depositors who want to transform their checkable deposits into cash. Similarly, it must guard against more checks clearing against it than are cleared in its favor, causing a net outflow of reserves. Bankers thus seek a balance between prudence and profit. The compromise is between assets that earn higher returns and highly liquid assets that earn no returns.

Before the financial crisis of 2007–2008, there was an interesting way in which banks could partly reconcile the goals of profit and liquidity: they could lend any temporary excess reserves that they had on deposit at the Fed to other commercial banks.

Before the crisis, normal day-to-day flows of funds to and between banks rarely left all banks with their exact levels of required reserves. Some banks had reserves in excess while others found themselves running short. There was thus an incentive for the banks that had excess reserves to lend them overnight to the banks that were deficient. These loans allowed the banks that were deficient to meet their reserve requirements while also allowing the banks making the loans to earn a little interest.

The market in which these loans were made is referred to as the federal funds market because it was the market for borrowing immediately available reserve balances at the Federal Reserve. The interest rate paid on these overnight loans is called the **federal funds rate**.

Lending excess reserves at the federal funds rate was also attractive to banks before the Financial Crisis because the Fed did not begin paying interest on excess reserves until 2008. So whatever interest could be earned by lending excess reserves at the federal funds rate exceeded the zero percent interest that banks would get from the Fed on reserves held on deposit overnight at a Federal Reserve Bank.

As the result of policy actions taken by the Federal Reserve during the Financial Crisis, nearly every bank in the United States ended up with a massive amount of excess reserves. This happened because the Fed wanted to increase liquidity in the financial system during the crisis. To do so,

it purchased trillions of dollars’ worth of financial assets from banks.

The banks then placed the large majority of the proceeds from selling securities to the Fed into their respective reserve accounts at the Fed. They did so to make sure that other banks, other financial firms, and their own clients all understood that they (the banks) were liquid and thus capable of honoring debt payments and withdrawal requests.

The reserves of commercial banks increased from \$43 billion in February 2008 to \$1,148 billion in March 2010. Total bank reserves held at the Fed exceeded total checkable deposits held by the banks. The severe distress in the financial system had turned the fractional reserve system into a 100-percent-plus reserve system!

The amount of money held as reserves overnight at the Fed remained massive through 2016. As a result, there were almost never any instances after 2010 where a bank needed to borrow reserves in the federal funds market. At the same time, nearly every bank had massive excess reserves. Those two factors implied a situation of low demand and large supply in the federal funds market. As a result, the equilibrium federal funds rate plunged to nearly zero while the volume of lending in the federal funds market shrank drastically due to there being hardly any demand for reserves.

It is possible that the federal funds market may some day revive if the volume of reserves fall. But as of the mid-2010s, the federal funds market appeared likely to remain a shadow of its previous self for many years to come.

It is still interesting, however, to give an example of how a federal funds loan affects banks’ balance sheets. We would show an overnight loan of reserves from the Surprise bank to the Wahoo bank as a decrease in reserves at the Surprise bank and an increase in reserves at the Wahoo bank. Ownership of reserves at the Federal Reserve Bank of Kansas City would change, but total reserves would not be affected. Exercise: Determine what other changes would be required on the Wahoo and Surprise banks’ balance sheets as a result of an overnight loan.

QUICK REVIEW 35.2

- ✓ Banks create money when they make loans; money vanishes when bank loans are repaid.
- ✓ New money is created when banks buy government bonds from the public; money disappears when banks sell government bonds to the public.
- ✓ Banks balance profitability and safety in determining their mix of earning assets and highly liquid assets.
- ✓ Although the Fed pays interest on excess reserves, banks may be able to obtain higher interest rates by temporarily lending the reserves to other banks in the federal funds market; the interest rate on such loans is the federal funds rate.

The Banking System: Multiple-Deposit Expansion

L035.4 Describe the multiple expansion of loans and money by the entire banking system.

Thus far we have seen that a single bank in a banking system can lend one dollar for each dollar of its excess reserves. The situation is different for all commercial banks as a group. We will find that the commercial banking system can lend—that is, can create money—by a multiple of its excess reserves. This multiple lending is accomplished even though each bank in the system can lend only “dollar for dollar” with its excess reserves.

How do these seemingly paradoxical results come about? To answer this question succinctly, we will make three simplifying assumptions:

- The reserve ratio for all commercial banks is 20 percent.
- Initially all banks are meeting this 20 percent reserve requirement exactly. No excess reserves exist; or, in the parlance of banking, they are “loaned up” (or “loaned out”) fully in terms of the reserve requirement.
- If any bank can increase its loans as a result of acquiring excess reserves, an amount equal to those excess reserves will be lent to one borrower, who will write a check for the entire amount of the loan and give it to someone else, who will deposit the check in another bank. This third assumption means that the worst thing possible happens to every lending bank—a check for the entire amount of the loan is drawn and cleared against it in favor of another bank.

The Banking System’s Lending Potential

Suppose a junkyard owner finds a \$100 bill while dismantling a car that has been on the lot for years. He deposits the \$100 in bank A, which adds the \$100 to its reserves. We will record only changes in the balance sheets of the various commercial banks. The deposit changes bank A’s balance sheet as shown by entries (a_1):

Multiple-Deposit Expansion Process Balance Sheet: Commercial Bank A			
Assets		Liabilities and net worth	
Reserves	\$+100 (a_1)	Checkable deposits	\$+100 (a_1)
	−80 (a_3)		
Loans	+80 (a_2)		+80 (a_2)
			−80 (a_3)

Recall from transaction 3 that this \$100 deposit of currency does not alter the money supply. While \$100 of

checkable-deposit money comes into being, it is offset by the \$100 of currency no longer in the hands of the public (the junkyard owner). But bank A *has* acquired excess reserves of \$80. Of the newly acquired \$100 in currency, 20 percent, or \$20, must be earmarked for the required reserves on the new \$100 checkable deposit, and the remaining \$80 goes to excess reserves. Remembering that a single commercial bank can lend only an amount equal to its excess reserves, we conclude that bank A can lend a maximum of \$80. When a loan for this amount is made, bank A’s loans increase by \$80 and the borrower gets an \$80 checkable deposit. We add these figures—entries (a_2)—to bank A’s balance sheet.

But now we make our third assumption: The borrower uses the full amount of the loan (\$80) to write a check (\$80) to someone else, and that person deposits the amount in bank B, a different bank. As we saw in transaction 6, bank A loses both reserves and deposits equal to the amount of the loan, as indicated in entries (a_3). The net result of these transactions is that bank A’s reserves now stand at +\$20 ($= \$100 - \80), loans at +\$80, and checkable deposits at +\$100 ($= \$100 + \$80 - \80). When the dust has settled, bank A is just meeting the 20 percent reserve ratio.

Recalling our previous discussion, we know that bank B acquires both the reserves and the deposits that bank A has lost. Bank B’s balance sheet is changed as in entries (b_1):

Multiple-Deposit Expansion Process Balance Sheet: Commercial Bank B			
Assets		Liabilities and net worth	
Reserves	\$+80 (b_1)	Checkable deposits	\$+80 (b_1)
	−64 (b_2)		
Loans	+64 (b_2)		+64 (b_2)
			−64 (b_3)

When the borrower’s check is drawn and cleared, bank A loses \$80 in reserves and deposits and bank B gains \$80 in reserves and deposits. But 20 percent, or \$16, of bank B’s new reserves must be kept as required reserves against the new \$80 in checkable deposits. This means that bank B has \$64 ($= \$80 - \16) in excess reserves. It can therefore lend \$64 [entries (b_2)]. When the new borrower writes a check for \$64 to buy a product, and the seller deposits the check in bank C, the reserves and deposits of bank B both fall by \$64 [entries (b_3)]. As a result of these transactions, bank B’s reserves now stand at +\$16 ($= \$80 - \64), loans at +\$64, and checkable deposits at +\$80 ($= \$80 + \$64 - \64). After all this, bank B is just meeting the 20 percent reserve requirement.

We are off and running again. Bank C acquires the \$64 in reserves and deposits lost by bank B. Its balance sheet changes as in entries (c_1):

Multiple-Deposit Expansion Process Balance Sheet: Commercial Bank C			
Assets		Liabilities and net worth	
Reserves	\$+64.00 (c_1)	Checkable deposits	\$+64.00 (c_1)
	-52.20 (c_3)		
Loans	+51.20 (c_2)		+51.20 (c_2)
			-51.20 (c_3)

Exactly 20 percent, or \$12.80, of these new reserves will be required reserves, the remaining \$51.20 being excess reserves. Hence, bank C can safely lend a maximum of \$51.20. Suppose it does [entries (c_2)]. And suppose the borrower writes a check for the entire amount (\$51.20) to a merchant who deposits it in another bank [entries (c_3)].

We could go ahead with this procedure by bringing banks D, E, F, G, . . . , N, and so on into the picture. In fact, the process will go on almost indefinitely, just as long as banks further down the line receive at least one penny in new reserves that they can use to back another round of lending and money creation. But we suggest that you work through the computations for banks D, E, and F to be sure you understand the procedure.

The entire analysis is summarized in Table 35.2. Data for banks D through N are supplied on their own rows so that you

may check your computations. The last row of the table consolidates into one row everything that happens for all banks down the line after bank N. Our conclusion is startling: On the basis of only \$80 in excess reserves (acquired by the banking system when someone deposited \$100 of currency in bank A), the entire commercial banking system is able to lend \$400, the sum of the amounts in column 4. The banking system can lend excess reserves by a multiple of 5 (= \$400/\$80) when the reserve ratio is 20 percent. Yet each single bank in the banking system is lending only an amount equal to its own excess reserves. How do we explain this? How can the banking system as a whole lend by a multiple of its excess reserves, when each individual bank can lend only dollar for dollar with its excess reserves?

The answer is that reserves lost by a single bank are not lost to the banking system as a whole. The reserves lost by bank A are acquired by bank B. Those lost by B are gained by C. C loses to D, D to E, E to F, and so forth. Although reserves can be, and are, lost by individual banks in the banking system, there is no loss of reserves for the banking system as a whole.

An individual bank can safely lend only an amount equal to its excess reserves, *but the commercial banking system can lend by a multiple of its collective excess reserves*. This contrast, incidentally, is an illustration of why it is imperative that we keep the fallacy of composition (Last Word, Chapter 1) firmly in mind. Commercial banks as a group can create money by lending in a manner much different from that of the individual banks in the group.

The Monetary Multiplier

L035.5 Define the monetary multiplier, explain how to calculate it, and demonstrate its relevance.

The **monetary multiplier** (or, less commonly, the *checkable deposit multiplier*) defines the relationship between any new excess reserves in the banking system and the magnified creation of new checkable-deposit money by banks as a group. It is a separate idea from the spending-income multiplier of Chapter 30 but shares some mathematical similarities. The spending-income multiplier exists because the expenditures of one household become some other household's income; the multiplier magnifies a change in initial spending into a larger change in GDP. The spending-income multiplier is the reciprocal of the MPS (the leakage into saving that occurs at each round of spending).

Similarly, the monetary multiplier exists because the reserves and deposits lost by one bank become reserves of another bank. It magnifies excess reserves into a larger creation of checkable-deposit money. The monetary multiplier m is the reciprocal of the required reserve ratio R (the leakage into required reserves that occurs at each step in the lending process). In short,

$$\text{Monetary multiplier} = \frac{1}{\text{required reserve ratio}}$$

or, in symbols,

$$m = \frac{1}{R}$$

In this formula, m represents the maximum amount of new checkable-deposit money that can be created by a single dollar of excess reserves, given the value of R . By multiplying the excess reserves E by m , we can find the maximum amount of new checkable-deposit money, D , that can be created by the banking system. That is,

$$\text{Maximum checkable-deposit creation} = \text{excess reserves} \times \text{monetary multiplier}$$

or, more simply,

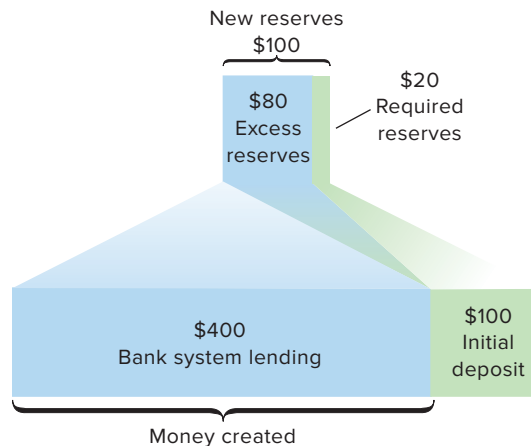

$$D = E \times m$$

In our example in Table 35.2, R is 0.20, so m is 5 ($= 1/0.20$). This implies that

$$D = \$80 \times 5 = \$400$$

Figure 35.1 depicts the final outcome of our example of a multiple-deposit expansion of the money supply. The initial deposit of \$100 of currency into the bank (lower right-hand box) creates new reserves of an equal amount (upper box). With a 20 percent reserve ratio, however, only \$20 of reserves

FIGURE 35.1 The outcome of the money expansion process. A deposit of \$100 of currency into a checking account creates an initial checkable deposit of \$100. If the reserve ratio is 20 percent, only \$20 of reserves is legally required to support the \$100 checkable deposit. The \$80 of excess reserves allows the banking system to create \$400 of checkable deposits through making loans. The \$100 of reserves supports a total of \$500 of money (\$100 + \$400).

are needed to “back up” this \$100 checkable deposit. The excess reserves of \$80 permit the creation of \$400 of new checkable deposits via the making of loans, confirming a monetary multiplier of 5. The \$100 of new reserves supports a total supply of money of \$500, consisting of the \$100 initial checkable deposit plus \$400 of checkable deposits created through lending.

Higher reserve ratios mean lower monetary multipliers and therefore less creation of new checkable-deposit money via loans; smaller reserve ratios mean higher monetary multipliers and thus more creation of new checkable-deposit money via loans. With a high reserve ratio, say, 50 percent, the monetary multiplier would be 2 ($= 1/0.5$), and in our example the banking system could create only \$100 ($= \50 of excess reserves $\times 2$) of new checkable deposits. With a low reserve ratio, say, 5 percent, the monetary multiplier would be 20 ($= 1/0.05$), and the banking system could create \$1,900 ($= \95 of excess reserves $\times 20$) of new checkable deposits.

You might experiment with the following two brainteasers to test your understanding of multiple credit expansion by the banking system:

- Rework the analysis in Table 35.2 (at least three or four steps of it) assuming the reserve ratio is 10 percent. What is the maximum amount of money the banking system can create upon acquiring \$100 in new reserves and deposits? (The answer is not \$800!)
- Suppose the banking system is loaned up and faces a 20 percent reserve ratio. Explain how it might have to reduce its outstanding loans by \$400 when a \$100 cash withdrawal from a checkable-deposit account forces one bank to draw down its reserves by \$100.

Banking, Leverage, and Financial Instability

Leverage Boosts Banking Profits but Makes the Banking System Less Stable. Time to Reduce Leverage?

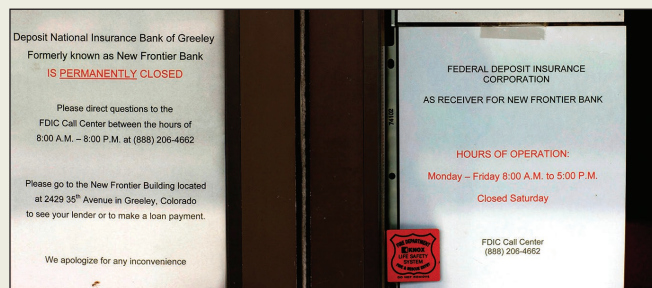

The term *leverage* is used in finance to describe how the use of borrowed money can magnify both profits and losses. To see how leverage works, first consider an investment opportunity that produces a 10 percent positive return if things go well but a 5 percent loss if things go poorly. Those rates of return imply that if a person invests \$100 of his own savings, he will end up with either \$110 if things go well or \$95 if things go badly. Put slightly differently, he will either gain \$10 or lose \$5 from where he started, with his own \$100 being used to fund the \$100 investment.

But now consider what happens to his potential returns if he uses borrowed money to provide “leverage.” In fact, let’s have him use a lot of leverage. To make the \$100 investment, he uses \$10 of his own savings and \$90 of borrowed money (which, for simplicity, we will assume that he can borrow at zero percent interest). If things go well, the investment will return \$110. He then must repay the \$90 loan. That will leave him with \$20 (= \$110 of investment return if things go well minus \$90 to repay the loan). That means that he will end up with \$20 if things go well and he uses leverage. Notice that this implies that if he uses leverage, he will get a 100 percent (= \$20 divided by \$10) return on the \$10 of his own savings that he himself invested. That, of course, is much nicer than a 10 percent return. In fact, it is 10 times as large—hence the term *leverage*. The use of borrowed money has massively increased the percentage rate of return if things go well.

Unfortunately, however, nothing in life is free. Leverage also magnifies the investor’s losses if things go wrong. To see this, note that if things go wrong in this example, the investor will end up turning \$100 into \$95. But then he has to pay back the \$90 that he borrowed. That will leave him with only \$5 (= \$95 investment return if things go badly minus \$90 to repay the loan). That implies that the investor will lose \$5 off of the \$10 of his own savings that he himself originally put into the investment. That is a 50 percent loss—10 times as much as the 5 percent loss that he would have sustained if he had used only his own money to make the \$100 investment. Thus, you can see that leverage increases both profits if things go well and losses if things go badly.

A modern bank uses a lot of leverage. In fact, only about 5 percent of the money that it invests comes from its shareholders and the money they paid to purchase ownership shares in the bank. The other 95 percent comes from borrowing, either by issuing bonds (about 25 percent) or by taking in checking and savings deposits (about 70 percent). It surprises many people, but checking and savings deposits are technically a type of loan made by depositors to their banks. So banks get 70 percent of their leverage and funding from money borrowed from depositors.

The problem with that much leverage is that it takes only very small losses to drive the bank into insolvency and a situation in which it cannot repay all of the money that it has borrowed because

© Bloomberg/Getty Images

the value of the bank’s assets has fallen below the value of the bank’s liabilities. Consider what would happen if for every \$100 invested by the bank, only \$94 returned. That by itself is a 6 percent rate of loss. But because the bank is borrowing \$95 of every \$100 that it invests, it will be driven into insolvency by that 6 percent loss because it is getting back less than the amount that it borrowed to fund the investment. With the investment returning only \$94, there won’t be enough money to pay off the \$95 that the bank borrowed!

So why do banks use this much leverage? Because it is very profitable for the bankers who run the banks. If things are going well, the leverage massively increases the banks’ profit rates—and bankers get paid bonuses based on those profit rates. On the other hand, if things go badly, bankers have come to expect bailouts in which the government uses taxpayer money to ensure that all of a bank’s liabilities are repaid. So from the perspective of the bankers, it’s “heads I win, tails you lose.”

One solution to these problems would be to require banks to use much less leverage. For every \$100 that a bank wants to invest, the bank could be required to raise \$30 from its shareholder owners so that it would only be borrowing the other \$70 through issuing bonds or by taking in checking and savings deposits. That would make the entire banking system much more stable because it would be very unlikely that for any \$100 invested into projects by the bank, less than \$70 would come back. Even if only \$71 came back, there would still be enough money to pay back the \$70 of borrowed money—and thus no need for the bank to go bankrupt or require a government bailout via the deposit insurance system.

Unfortunately, however, bankers have lobbied strongly and successfully against any legal attempts to require lower leverage levels. So the current regulatory system relies instead on bank supervisors who attempt to prevent the banks from making bad loans. That system was unable to prevent the 2007–2008 financial crisis and a number of economists argue that until leverage is reduced, no amount of bank supervision will be sufficient to prevent another financial crisis because with massive leverage, even a small loss can destroy a bank.

Reversibility: The Multiple Destruction of Money

The process we have described is reversible. Just as checkable-deposit money is created when banks make loans, checkable-deposit money is destroyed when loans are paid off. Loan repayment, in effect, sets off a process of multiple destruction of money the opposite of the multiple creation process. Because loans are both made and paid off in any period, the direction of the loans, checkable deposits, and money supply in a given period will depend on the net effect of the two processes. If the dollar amount of loans made in some period exceeds the dollar amount of loans paid off, checkable deposits will expand and the money supply will increase. But if the dollar amount of loans is less than the dollar amount of loans paid off, checkable deposits will contract and the money supply will decline.

Historically, one of the Fed's main ways of influencing the economy was by changing the supply of bank money. But

the Fed has other ways, as well, which we will explore in the next chapter.

QUICK REVIEW 35.3

- ✓ A single bank in a multibank system can safely lend (create money) by an amount equal to its excess reserves; the banking system can lend (create money) by a multiple of its excess reserves.
- ✓ The monetary multiplier is the reciprocal of the required reserve ratio; it is the multiple by which the banking system can expand the money supply for each dollar of excess reserves.
- ✓ The monetary multiplier works in both directions; it applies to money destruction from the payback of loans as well as the money creation from the making of loans.

SUMMARY

L035.1 Discuss why the U.S. banking system is called a “fractional reserve” system.

Modern banking systems are fractional reserve systems: Only a fraction of checkable deposits is backed by currency.

L035.2 Explain the basics of a bank's balance sheet and the distinction between a bank's actual reserves and its required reserves.

The operation of a commercial bank can be understood through its balance sheet, where assets equal liabilities plus net worth.

Commercial banks keep required reserves on deposit in a Federal Reserve Bank or as vault cash. These required reserves are equal to a specified percentage of the commercial bank's checkable-deposit liabilities. Excess reserves are equal to actual reserves minus required reserves.

Banks lose both reserves and checkable deposits when checks are drawn against them.

L035.3 Describe how a bank can create money.

Commercial banks create money—checkable deposits, or checkable-deposit money—when they make loans. They convert IOUs, which are *not* money, into checkable-deposits, which *are* money. Money is destroyed when lenders repay bank loans.

The ability of a single commercial bank to create money by lending depends on the size of its excess reserves. Generally speaking, a commercial bank can lend only an amount equal to its excess reserves. Money creation is thus limited because, in all likelihood, checks drawn by borrowers will be deposited in other banks, causing a loss of reserves and deposits to the lending bank equal to the amount of money that it has lent.

Rather than making loans, banks may decide to use excess reserves to buy bonds from the public. In doing so, banks merely credit the checkable-deposit accounts of the bond sellers, thus creating checkable-deposit money. Money vanishes when banks sell bonds to the public because bond buyers must draw down their checkable-deposit balances to pay for the bonds.

Banks earn interest by making loans and by purchasing bonds; they maintain liquidity by holding cash and excess reserves. The Fed currently pays interest on excess reserves. But prior to the financial crisis of 2007–2008, banks could obtain a higher interest rate by lending excess reserves on an overnight basis to banks that were short of required reserves. Those loans were made in the federal funds market, and the interest rate on those loans was called the federal funds rate. But policy actions during the crisis left virtually every bank in the United States with large amounts of excess reserves and thus no need to borrow any from another bank. The federal funds market has consequently shriveled in size and the federal funds rate has plunged to nearly zero due to low demand for excess reserves interacting with a massive supply of excess reserves.

L035.4 Describe the multiple expansion of loans and money by the entire banking system.

The commercial banking system as a whole can lend by a multiple of its excess reserves because the system as a whole cannot lose reserves. Individual banks, however, can lose reserves to other banks in the system.

L035.5 Define the monetary multiplier, explain how to calculate it, and demonstrate its relevance.

The multiple by which the banking system can lend on the basis of each dollar of excess reserves is the reciprocal of the reserve ratio. This multiple credit expansion process is reversible.

DISCUSSION QUESTIONS

1. Explain why merchants accepted gold receipts as a means of payment even though the receipts were issued by goldsmiths, not the government. What risk did goldsmiths introduce into the payments system by issuing loans in the form of gold receipts? **L035.1**
2. Why is the banking system in the United States referred to as a fractional reserve bank system? What is the role of deposit insurance in a fractional reserve system? **L035.1**
3. What is the difference between an asset and a liability on a bank's balance sheet? How does net worth relate to each? Why must a balance sheet always balance? What are the major assets and claims on a commercial bank's balance sheet? **L035.2**
4. Why does the Federal Reserve require commercial banks to have reserves? Explain why reserves are an asset to commercial banks but a liability to the Federal Reserve Banks. What are excess reserves? How do you calculate the amount of excess reserves held by a bank? What is the significance of excess reserves? **L035.2**
5. "Whenever currency is deposited in a commercial bank, cash goes out of circulation and, as a result, the supply of money is reduced." Do you agree? Explain why or why not. **L035.2**
6. "When a commercial bank makes loans, it creates money; when loans are repaid, money is destroyed." Explain. **L035.3**
7. Suppose that Mountain Star Bank discovers that its reserves will temporarily fall slightly below those legally required. How might it temporarily remedy this situation through the federal funds market? Now assume Mountain Star finds that its reserves will be substantially and permanently deficient. What remedy is available to this bank? (Hint: Recall your answer to discussion question 6.) **L035.3**
8. Explain why a single commercial bank can safely lend only an amount equal to its excess reserves, but the commercial banking system as a whole can lend by a multiple of its excess reserves. What is the monetary multiplier, and how does it relate to the reserve ratio? **L035.4, L035.5**
9. How would a decrease in the reserve requirement affect the (a) size of the monetary multiplier, (b) amount of excess reserves in the banking system, and (c) extent to which the system could expand the money supply through the creation of checkable deposits via loans? **L035.5**
10. **LAST WORD** Does leverage increase the total size of the gain or loss from an investment, or just the percentage rate of return on the part of the investment amount that was not borrowed? How would lowering leverage make the financial system more stable?

REVIEW QUESTIONS

1. A goldsmith has \$2 million of gold in his vaults. He issues \$5 million in gold receipts. His gold holdings are what fraction of the paper money (gold receipts) he has issued? **L035.1**
 - a. 1/10.
 - b. 1/5.
 - c. 2/5.
 - d. 5/5.
2. A commercial bank has \$100 million in checkable-deposit liabilities and \$12 million in actual reserves. The required reserve ratio is 10 percent. How big are the bank's excess reserves? **L035.2**
 - a. \$100 million.
 - b. \$88 million.
 - c. \$12 million.
 - d. \$2 million.
3. The actual reason that banks must hold required reserves is: **L035.2**
 - a. To enhance liquidity and deter bank runs.
 - b. To help fund the Federal Deposit Insurance Corporation, which insures bank deposits.
 - c. To give the Fed control over the lending ability of commercial banks.
 - d. To help increase the number of bank loans.
4. A single commercial bank in a multibank banking system can lend only an amount equal to its initial preloan _____. **L035.3**
 - a. Total reserves.

Some newspaper commentators have stated that the chairperson of the Federal Reserve Board (currently Janet Yellen) is the second most powerful person in the United States, after the U.S. president. That is undoubtedly an exaggeration because the chair has only a single vote on the 7-person Federal Reserve Board and 12-person Federal Open Market Committee. But there can be no doubt about

the chair's influence as well as the overall importance of the Federal Reserve and the **monetary policy** that it conducts. Such policy consists of deliberate changes in the money supply to influence interest rates and thus the total level of spending in the economy. The goal of monetary policy is to achieve and maintain price-level stability, full employment, and economic growth.

Interest Rates

LO36.1 Discuss how the equilibrium interest rate is determined in the market for money.

The Fed's primary influence on the economy in normal economic times is through its ability to change the money supply (M_1 and M_2) and therefore affect interest rates. Interest rates can be thought of in several ways. Most basically, **interest** is the price paid for the use of money. It is also the price that borrowers need to pay lenders for transferring purchasing power to the future. And it can be thought of as the amount of money that must be paid for the use of \$1 for 1 year. Although there are many different interest rates that vary by purpose, size, risk, maturity, and taxability, we will simply speak of *the* interest rate unless stated otherwise.

Let's see how the interest rate is determined. Because it is a "price," we again turn to demand and supply analysis for the answer.

The Demand for Money

Why does the public want to hold some of its wealth as *money*? There are two main reasons: to make purchases with it and to hold it as an asset.

Transactions Demand, D_t People hold money because it is convenient for purchasing goods and services. Households usually are paid once a week, every 2 weeks, or monthly, whereas their expenditures are less predictable and typically more frequent. So households must have enough money on hand to buy groceries and pay mortgage and utility bills. Nor are business revenues and expenditures simultaneous. Businesses need to have money available to pay for labor, materials, power, and other inputs. The demand for money as a medium of exchange is called the **transactions demand for money**.

The level of nominal GDP is the main determinant of the amount of money demanded for transactions. The larger the total money value of all goods and services exchanged in the economy, the larger the amount of money needed to negotiate those transactions. The transactions demand for money varies directly with nominal GDP. We specify *nominal GDP* because households and firms will want more money for transactions if prices rise or if real output increases. In both instances a larger dollar volume will be needed to accomplish the desired transactions.

In **Figure 36.1a (Key Graph)**, we graph the quantity of money demanded for transactions against the interest rate. For simplicity, let's assume that the amount demanded depends exclusively on the level of nominal GDP and is independent of the interest rate. (In reality, higher interest rates are associated with slightly lower volumes of money demanded for transactions.) Our simplifying assumption allows us to graph the transactions demand, D_t , as a vertical line. This demand curve is positioned at \$100 billion, on the assumption that each dollar held for transactions purposes is spent an average of three times per year and that nominal GDP is \$300 billion. Thus the public needs \$100 billion (= \$300 billion/3) to purchase that GDP.

Asset Demand, D_a The second reason for holding money derives from money's function as a store of value. People may hold their financial assets in many forms, including corporate stocks, corporate or government bonds, or money. To the extent they want to hold money as an asset, there is an **asset demand for money**.

People like to hold some of their financial assets as money (apart from using it to buy goods and services) because money is the most liquid of all financial assets; it is immediately usable for purchasing other assets when opportunities arise. Money is also an attractive asset to hold when the prices of other assets such as bonds are expected to decline. For example, when the price of a bond falls, the bondholder who sells the bond prior to the payback date of the full

principal will suffer a loss (called a *capital loss*). That loss will partially or fully offset the interest received on the bond. Holding money presents no such risk of capital loss from changes in interest rates.

The disadvantage of holding money as an asset is that it earns no or very little interest. Checkable deposits pay either no interest or lower interest rates than bonds. Currency itself earns no interest at all.

Knowing these advantages and disadvantages, the public must decide how much of its financial assets to hold as money, rather than other assets such as bonds. The answer depends primarily on the rate of interest. A household or a business incurs an opportunity cost when it holds money; in both cases, interest income is forgone or sacrificed. If a bond pays 6 percent interest, for example, holding \$100 as cash or in a noninterest checkable account costs \$6 per year of forgone income.

The amount of money demanded as an asset therefore varies inversely with the rate of interest (which is the opportunity cost of holding money as an asset). When the interest rate rises, being liquid and avoiding capital losses becomes more costly. The public reacts by reducing its holdings of money as an asset. When the interest rate falls, the cost of being liquid and avoiding capital losses also declines. The public therefore increases the amount of financial assets that it wants to hold as money. This inverse relationship just described is shown by D_a in Figure 36.1b.

Total Money Demand, D_m As shown in Figure 36.1, we find the **total demand for money, D_m** , by horizontally adding the asset demand to the transactions demand. The resulting downsloping line in Figure 36.1c represents the total amount of money the public wants to hold, both for transactions and as an asset, at each possible interest rate.

Recall that the transactions demand for money depends on the nominal GDP. A change in the nominal GDP—working through the transactions demand for money—will shift the total money demand curve. Specifically, an increase in nominal GDP means that the public wants to hold a larger amount of money for transactions, and that extra demand will shift the total money demand curve to the right. In contrast, a decline in the nominal GDP will shift the total money demand curve to the left. As an example, suppose nominal GDP increases from \$300 billion to \$450 billion and the average dollar held for transactions is still spent three times per year. Then the transactions demand curve will shift from \$100 billion (= \$300 billion/3) to \$150 billion (= \$450 billion/3). The total money demand curve will then lie \$50 billion farther to the right at each possible interest rate.

The Equilibrium Interest Rate

We can combine the demand for money with the supply of money to determine the equilibrium rate of interest. In Figure 36.1c, the vertical line, S_m , represents the money

FIGURE 36.1 The demand for money, the supply of money, and the equilibrium interest rate. The total demand for money D_m is determined by horizontally adding the asset demand for money D_a to the transactions demand D_t . The transactions demand is vertical because it is assumed to depend on nominal GDP rather than on the interest rate. The asset demand varies inversely with the interest rate because of the opportunity cost involved in holding currency and checkable deposits that pay no interest or very low interest. Combining the money supply (stock) S_m with the total money demand D_m portrays the market for money and determines the equilibrium interest rate i_e .

QUICK QUIZ FOR FIGURE 36.1

- In this graph, at the interest rate i_e (5 percent):
 - the amount of money demanded as an asset is \$50 billion.
 - the amount of money demanded for transactions is \$200 billion.
 - bond prices will decline.
 - \$100 billion is demanded for transactions, \$100 billion is demanded as an asset, and the money supply is \$200 billion.
- In this graph, at an interest rate of 10 percent:
 - no money will be demanded as an asset.
 - total money demanded will be \$200 billion.
 - the Federal Reserve will supply \$100 billion of money.
 - there will be a \$100 billion shortage of money.
- Curve D_a slopes downward because:
 - lower interest rates increase the opportunity cost of holding money.
 - lower interest rates reduce the opportunity cost of holding money.
 - the asset demand for money varies directly (positively) with the interest rate.
 - the transactions-demand-for-money curve is perfectly vertical.
- Suppose the supply of money declines to \$100 billion. The equilibrium interest rate would:
 - fall, the amount of money demanded for transactions would rise, and the amount of money demanded as an asset would decline.
 - rise, and the amounts of money demanded both for transactions and as an asset would fall.
 - fall, and the amounts of money demanded both for transactions and as an asset would increase.
 - rise, the amount of money demanded for transactions would be unchanged, and the amount of money demanded as an asset would decline.

Answers: 1. d; 2. a; 3. b; 4. d

supply. It is a vertical line because the monetary authorities and financial institutions have provided the economy with some particular stock of money. Here it is \$200 billion.

Just as in a product market or a resource market, the intersection of demand and supply determines the equilibrium price in the market for money. In Figure 36.1, this equilibrium price is the equilibrium interest rate, i_e . At this interest rate, the quantity of money demanded (= \$200 billion) equals the quantity of money supplied (= \$200 billion). The equilibrium interest rate can be thought of as the market-determined price that borrowers must pay for using someone else's money over some period of time.

Changes in the demand for money, the supply of money, or both can change the equilibrium interest rate. For reasons that will soon become apparent, we are most interested in changes in the supply of money. The important generalization is this: An increase in the supply of money will lower the equilibrium interest rate; a decrease in the supply of money will raise the equilibrium interest rate.

Interest Rates and Bond Prices

Interest rates and bond prices are inversely related. When the interest rate increases, bond prices fall; when the interest rate

falls, bond prices rise. Why so? First understand that bonds are bought and sold in financial markets and that the price of bonds is determined by bond demand and bond supply.

Suppose that a bond with no expiration date pays a fixed \$50 annual interest payment and is selling for its face value of \$1,000. The interest yield on this bond is 5 percent:

$$\frac{\$50}{\$1,000} = 5\% \text{ interest yield}$$

Now suppose the interest rate in the economy rises to $7\frac{1}{2}$ percent from 5 percent. Newly issued bonds will pay \$75 per \$1,000 lent. Older bonds paying only \$50 will not be salable at their \$1,000 face value. To compete with the $7\frac{1}{2}$ percent bond, the price of this bond will need to fall to \$667 to remain competitive. The \$50 fixed annual interest payment will then yield $7\frac{1}{2}$ percent to whoever buys the bond:

$$\frac{\$50}{\$667} = 7\frac{1}{2}\%$$

Next suppose that the interest rate falls to $2\frac{1}{2}$ percent from the original 5 percent. Newly issued bonds will pay \$25 on \$1,000 loaned. A bond paying \$50 will be highly attractive. Bond buyers will bid up its price to \$2,000, where the yield will equal $2\frac{1}{2}$ percent:

$$\frac{\$50}{\$2,000} = 2\frac{1}{2}\%$$

The point is that bond prices fall when the interest rate rises and rise when the interest rate falls. There is an inverse relationship between the interest rate and bond prices.

QUICK REVIEW 36.1

- ✓ People demand money for transaction and asset purposes.
- ✓ The total demand for money is the sum of the transactions and asset demands; it is graphed as an inverse relationship (downsloping line) between the interest rate and the quantity of money demanded.
- ✓ The equilibrium interest rate is determined by money demand and supply; it occurs when people are willing to hold the exact amount of money being supplied by the monetary authorities.
- ✓ Interest rates and bond prices are inversely related.

The Consolidated Balance Sheet of the Federal Reserve Banks

GLOBAL PERSPECTIVE 36.1

Central Banks, Selected Nations

The monetary policies of the world's major central banks are often in the international news. Here are some of their official names, along with a few of their popular nicknames.

Australia: Reserve Bank of Australia (RBA)
Canada: Bank of Canada
Euro Zone: European Central Bank (ECB)
Japan: The Bank of Japan (BOJ)
Mexico: Banco de Mexico (Mex Bank)

Sweden: Sveriges Riksbank
United Kingdom: Bank of England
United States: Federal Reserve System (the Fed)

be effective. The 12 Federal Reserve Banks together constitute the U.S. “central bank,” nicknamed the “Fed.” (Global Perspective 36.1 also lists some of the other central banks in the world, along with their nicknames.)

The Fed’s balance sheet helps us consider how the Fed conducts monetary policy. Table 36.1 consolidates the pertinent assets and liabilities of the 12 Federal Reserve Banks as of April 6, 2016. You will see that some of the Fed’s assets and liabilities differ from those found on the balance sheet of a commercial bank.

Assets

The two main assets of the Federal Reserve Banks are securities and loans to commercial banks. (Again, we will simplify by referring only to *commercial banks*, even though the analysis also applies to *thrifts*—savings and loans, mutual savings banks, and credit unions.)

Securities The securities shown in Table 36.1 are bonds that have been purchased by the Federal Reserve Banks. The majority (\$2,341 billion) consists of Treasury bills (short-term securities), Treasury notes (mid-term securities), and Treasury bonds (long-term securities) issued by the U.S. government to finance past budget deficits. These securities are part of the public debt—the money borrowed by the federal government. The Federal Reserve Banks bought these securities from commercial banks and the public through open-market operations. Although they are an important source of interest income to the Federal Reserve Banks, they are mainly bought and sold to influence the size of commercial bank reserves and, therefore, the ability of those banks to create

money by lending. The Fed's securities holdings also include a large amount (\$1,753 billion) of mortgage-backed securities purchased during and after the mortgaged debt crisis to bail out mortgage lenders.

Loans to Commercial Banks For reasons that will soon become clear, commercial banks occasionally borrow from Federal Reserve Banks. The IOUs that commercial banks give these “bankers’ banks” in return for loans are listed on the Federal Reserve balance sheet as “Loans to commercial banks.” They are assets to the Fed because they are claims against the commercial banks. To commercial banks, of course, these loans are liabilities in that they must be repaid. Through borrowing in this way, commercial banks can increase their reserves.

Liabilities

On the “liabilities and net worth” side of the Fed's consolidated balance sheet, three entries are noteworthy: reserves, Treasury deposits, and Federal Reserve Notes.

Reserves of Commercial Banks The Fed requires that the commercial banks hold reserves against their checkable deposits. The Fed pays interest on these required reserves and also on the excess reserves that banks choose to hold at the Fed. Banks held a huge amount of these excess reserves at the Fed during the severe recession of 2007–2009 and on through 2016 as the economy recovered only sluggishly after the Great Recession. Banks simply were highly concerned that loans to some private borrowers might not get paid back. When held in the Federal Reserve Banks, these reserves are listed as a liability on the Fed's balance sheet. They are assets on the books of the commercial banks, which still own them even though they are deposited at the Federal Reserve Banks.

Treasury Deposits The U.S. Treasury keeps deposits in the Federal Reserve Banks and draws checks on them to pay its obligations. To the Treasury these deposits are assets; to the Federal Reserve Banks they are liabilities. The Treasury creates and replenishes these deposits by depositing tax

receipts and money borrowed from the public or from the commercial banks through the sale of bonds.

Federal Reserve Notes Outstanding As we have seen, the supply of paper money in the United States consists of Federal Reserve Notes issued by the Federal Reserve Banks. When this money is circulating outside the Federal Reserve Banks, it constitutes claims against the assets of the Federal Reserve Banks. The Fed thus treats these notes as a liability.

QUICK REVIEW 36.2

- ✓ The two main assets of the Federal Reserve Banks are securities and loans to commercial banks. Most of the securities are bills, notes, and bonds issued by the U.S. Treasury to finance past federal budget deficits.
- ✓ The three major liabilities of the Federal Reserve Banks are reserves of commercial banks, Treasury deposits, and outstanding Federal Reserve notes.

Tools of Monetary Policy

L036.3 List and explain the goals and tools of monetary policy. With this look at the Federal Reserve Banks' consolidated balance sheet, we can now explore how the Fed can influence the money-creating abilities of the commercial banking system. The Fed has four main tools of monetary control it can use to alter the reserves of commercial banks:

- Open-market operations
- The reserve ratio
- The discount rate
- Interest on reserves

Open-Market Operations

Bond markets are “open” to all buyers and sellers of corporate and government bonds (securities). The Federal Reserve

is the largest single holder of U.S. government securities. The U.S. government, not the Fed, issued these Treasury bills, Treasury notes, and Treasury bonds to finance past budget deficits. Over the decades, the Fed has purchased these securities from major financial institutions that buy and sell government and corporate securities for themselves or their customers.

The Fed's **open-market operations** consist of bond market transactions in which the Fed either buys or sells government bonds (U.S. securities) outright, or uses them as collateral on loans of money. Assets—in this case, government bonds—serve as **collateral** when they are pledged by a borrower to a lender with the understanding that the lender will get to keep the assets if the borrower fails to repay the loan. Until the mortgage debt crisis of 2008, the Fed only bought or sold government bonds outright when conducting open-market operations. But in recent years it has added loans of money collateralized with government bonds to its open-market operations policy arsenal.

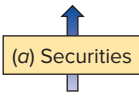

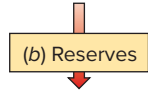

The conduit for the Fed's open-market operations is the trading desk of the New York Federal Reserve bank. When the Fed buys or sells government bonds, the trading desk at the New York Fed interacts exclusively with a group of 23 or so large financial firms called "primary dealers." When the Fed borrow or lends money via collateralized transactions known as *repos* and *reverse repos*, the trading desk at the New York Fed interacts with a much larger group of financial institutions that consists of 20 commercial banks (such as Bank of America and Goldman Sachs) plus 41 nonbank financial institutions: 28 investment management companies (such as Fidelity and Vanguard) plus 13 government-sponsored financial entities (such as the Federal Home Loan Bank of Boston and the Federal National Mortgage Association, or Fannie Mae).

Buying Securities Suppose that the Fed decides to have the Federal Reserve Banks buy government bonds. They can purchase these bonds either from commercial banks or from the public. In both cases the reserves of the commercial banks will increase.

From Commercial Banks When Federal Reserve Banks buy government bonds *from commercial banks*,

- (a) The commercial banks give up part of their holdings of securities (the government bonds) to the Federal Reserve Banks.
- (b) The Federal Reserve Banks, in paying for these securities, place newly created reserves in the accounts of the commercial banks at the Fed. (These reserves are created "out of thin air," so to speak!) The reserves of the commercial banks go up by the amount of the purchase of the securities.

We show these outcomes as (a) and (b) on the following consolidated balance sheets of the commercial banks and the Federal Reserve Banks:

Fed Buys Bonds from Commercial Banks Federal Reserve Banks	
Assets	Liabilities and net worth
+ Securities (a)	+ Reserves of commercial banks (b)
	
Commercial Banks	
Assets	Liabilities and net worth
- Securities (a) + Reserves (b)	

The upward arrow shows that securities have moved from the commercial banks to the Federal Reserve Banks. So we enter "– Securities" (minus securities) in the asset column of the balance sheet of the commercial banks. For the same reason, we enter "+ Securities" in the asset column of the balance sheet of the Federal Reserve Banks.

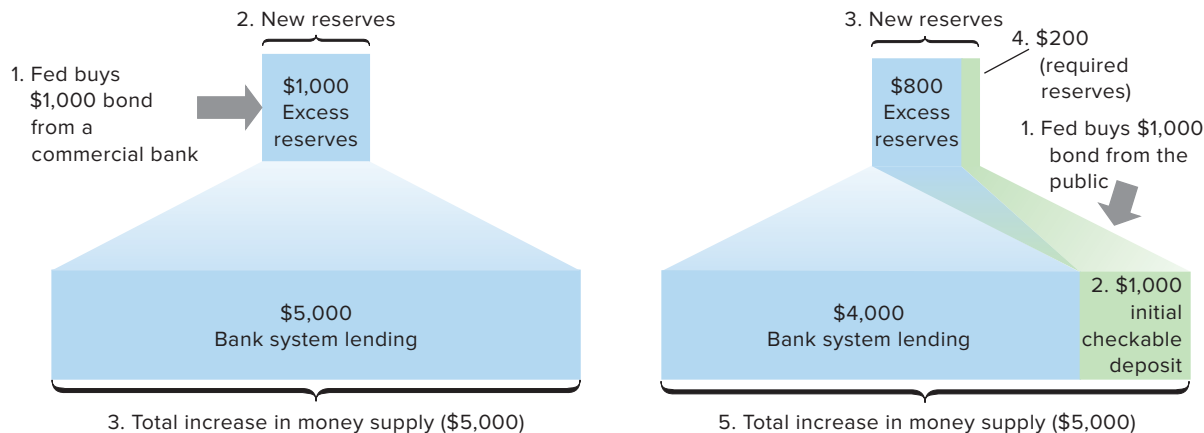

The downward arrow indicates that the Federal Reserve Banks have provided reserves to the commercial banks. So we enter "+ Reserves" in the asset column of the balance sheet for the commercial banks. In the liability column of the balance sheet of the Federal Reserve Banks, the plus sign indicates that although commercial bank reserves have increased, they are a liability to the Federal Reserve Banks because the reserves are owned by the commercial banks.

What is most important about this transaction is that when Federal Reserve Banks purchase securities from commercial banks, they increase the reserves in the banking system, which then increases the lending ability of the commercial banks.

From the Public The effect on commercial bank reserves is much the same when Federal Reserve Banks purchase securities from the general public. Suppose the Gristly Meat Packing Company has government bonds that it sells in the open market to the Federal Reserve Banks. The transaction has several elements:

- (a) Gristly gives up securities to the Federal Reserve Banks and gets in payment a check drawn by the Federal Reserve Banks on themselves.
- (b) Gristly promptly deposits the check in its account with the Wahoo bank.

FIGURE 36.2 The Federal Reserve's purchase of bonds and the expansion of the money supply. Assuming all banks are loaned up initially, a Federal Reserve purchase of a \$1,000 bond from either a commercial bank or the public can increase the money supply by \$5,000 when the reserve ratio is 20 percent. In the upper panel of the diagram, the purchase of a \$1,000 bond from a commercial bank creates \$1,000 of excess reserves that support a \$5,000 expansion of checkable deposits through loans. In the lower panel, the purchase of a \$1,000 bond from the public creates a \$1,000 checkable deposit but only \$800 of excess reserves because \$200 of reserves is required to "back up" the \$1,000 new checkable deposit. The commercial banks can therefore expand the money supply by only \$4,000 by making loans. This \$4,000 of checkable-deposit money plus the new checkable deposit of \$1,000 equals \$5,000 of new money.

- (c) The Wahoo bank sends this check against the Federal Reserve Banks to a Federal Reserve Bank for collection. As a result, the Wahoo bank enjoys an increase in its reserves.

To keep things simple, we will dispense with showing the balance sheet changes resulting from the Fed's sale or purchase of bonds from the public. But two aspects of this transaction are particularly important. First, as with Federal Reserve purchases of securities directly from commercial banks, the purchases of securities from the public increase the lending ability of the commercial banking system. Second, the supply of money is directly increased by the Federal Reserve Banks' purchase of government bonds (aside from any expansion of the money supply that may occur from the increase in commercial bank reserves). This direct increase in the money supply has taken the form of an increased amount of checkable deposits in the economy as a result of Gristly's deposit.

The Federal Reserve Banks' purchases of securities from the commercial banking system differ slightly from their purchases of securities from the public. If we assume that all commercial banks are loaned up initially, Federal Reserve bond purchases *from commercial banks* increase the actual reserves and excess reserves of commercial banks by the entire amount of the bond purchases. As shown in the left panel in Figure 36.2, a \$1,000 bond purchase from a commercial bank increases both the actual and the excess reserves of the commercial bank by \$1,000.

In contrast, Federal Reserve Bank purchases of bonds from the public increase actual reserves but also increase checkable deposits when the sellers place the Fed's check into their personal checking accounts. As shown in the right

panel of Figure 36.2, a \$1,000 bond purchase from the public would increase checkable deposits by \$1,000 and hence the actual reserves of the loaned-up banking system by the same amount. But with a 20 percent reserve ratio applied to the \$1,000 checkable deposit, the excess reserves of the banking system would be only \$800 since \$200 of the \$1,000 would have to be held as reserves.

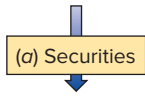

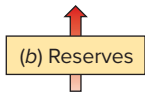

However, in both transactions the end result is the same: When Federal Reserve Banks buy securities in the open market, commercial banks' reserves are increased. When the banks lend out an amount equal to their excess reserves, the nation's money supply will rise. Observe in Figure 36.2 that a \$1,000 purchase of bonds by the Federal Reserve results in a potential of \$5,000 of additional money, regardless of whether the purchase was made from commercial banks (left panel) or from the general public (right panel).

Selling Securities As you may suspect, when the Federal Reserve Banks sell government bonds, commercial banks' reserves are reduced. Let's see why.

To Commercial Banks When the Federal Reserve Banks sell securities in the open market to commercial banks,

- The Federal Reserve Banks give up securities that the commercial banks acquire.
- The commercial banks pay for those securities by drawing checks against their deposits—that is, against their reserves—in Federal Reserve Banks. The Fed collects on those checks by reducing the commercial banks' reserves accordingly.

The balance-sheet changes—again identified by (a) and (b)—appear as shown in the following balance sheets. The reduction in commercial bank reserves is indicated by the minus signs before the appropriate entries.

Assets	Liabilities and net worth
- Securities (a)	- Reserves of commercial banks (b)
	

Commercial Banks	
Assets	Liabilities and net worth
- Reserves (b) + Securities (a)	

To the Public When the Federal Reserve Banks sell securities to the public, the outcome is much the same. Let's put the Gristly Company on the buying end of government bonds that the Federal Reserve Banks are selling:

- (a) The Federal Reserve Banks sell government bonds to Gristly, which pays with a check drawn on the Wahoo bank.
- (b) The Federal Reserve Banks clear this check against the Wahoo bank by reducing Wahoo's reserves.
- (c) The Wahoo bank returns the canceled check to Gristly, reducing Gristly's checkable deposit accordingly.

Federal Reserve bond sales of \$1,000 to the commercial banking system reduce the system's actual and excess reserves by \$1,000. But a \$1,000 bond sale to the public reduces excess reserves by \$800 because the public's checkable-deposit money is also reduced by \$1,000 by the sale. Since the commercial banking system's outstanding checkable deposits are reduced by \$1,000, banks need to keep \$200 less in reserves.

Whether the Fed sells bonds to the public or to commercial banks, the result is the same: When Federal Reserve Banks sell securities in the open market, commercial bank reserves are reduced. If all excess reserves are already lent out, this decline in commercial bank reserves produces a decline in the nation's money supply. In our example, a \$1,000 sale of government securities results in a \$5,000 decline in the money supply whether the sale is made to commercial banks or to the general public. You can verify this by reexamining Figure 36.2 and tracing the effects of a *sale* of a \$1,000 bond by the Fed either to commercial banks or to the public.

What makes commercial banks and the public willing to sell government securities to, or buy them from, Federal Reserve Banks? The answer lies in the price of bonds and their interest yields. We know that bond prices and interest rates are inversely related. When the Fed buys government bonds, the demand for them increases. Government bond prices rise, and their interest yields decline. The higher bond prices and their lower interest yields prompt banks, securities firms, and individual holders of government bonds to sell them to the Federal Reserve Banks.

When the Fed sells government bonds, the additional supply of bonds in the bond market lowers bond prices and raises their interest yields, making government bonds attractive purchases for banks and the public.

Repos and Reverse Repos In addition to bond purchases and sales, the Fed can also alter the supply of money through collateralized loans known as repos and reverse repos.

A money loan is said to be collateralized when an asset is pledged by the borrower to reduce the financial risk of default (failure to repay) that has to be borne by the lender. As an example, consider home mortgages. If Paul takes out a home mortgage, the home that he is buying will serve as collateral for his home mortgage loan. If Paul fails to repay the loan, ownership of the home will pass to the lender, who can then sell the home to get back most or all of the money that it lent to Paul.

Because the use of collateral greatly reduces the financial consequences of default for lenders, interest rates on collateralized loans such as home mortgages and auto loans are much lower than on uncollateralized loans such as credit card debt (where if a person defaults, there is no collateral that the lender can claim to help offset the loss).

Repos and reverse repos are short-hand names for repurchase agreements, discussed in the nearby Consider This box. In essence, repos and reverse repos are collateralized loans in which government securities serve as collateral. When the Fed undertakes a **repo** transaction, it makes a loan of money in exchange for government bonds being posted as collateral. The Fed's repo loans are normally overnight loans but can last as long as 65 business days. The Fed holds the bonds posted as collateral until the loan is either repaid or goes into default. If the money is repaid on time, the Fed returns the bonds to the borrower. If the money is not repaid on time, the Fed keeps the bonds.

Reverse repo transactions are repos in reverse. Instead of the Fed lending money against bond collateral, it is the Fed that posts government bonds as collateral when borrowing money from financial institutions.

The key point is that repos involve the Fed lending money into the financial system whereas reverse repos involve the Fed borrowing money out of the financial system. That means that repos are like open-market purchases of bonds (because both increase the money supply) while reverse repos are like open-market sales of bonds (because both decrease

Repo, Man

While *repos* refer to repurchase agreements, not repossessions, they are similar to repossessions because they also involve collateralized loans. Consider car loans, which are collateralized with cars. You get your car; your lender gets your payments. If you stop making your payments, your lender will send out a repo man to collect the collateral.

A repurchase agreement consists of two successive asset transactions—an initial sale followed by a repurchase—that together are equivalent to a collateralized loan. As an example, suppose Bank A wants to enter into a repurchase agreement with the Fed. Bank A would sell, for instance, \$10 million of Treasury bonds to the Fed with the stipulation that it will repurchase those bonds from the Fed the next day. The repurchase price will be \$10 million plus a small additional amount of money, say \$50, that is equivalent to an interest payment on what amounts to an overnight collateralized loan.

To see why the repo is equivalent to an overnight collateralized loan, note that while the repurchase agreement is in effect overnight, the Fed owns the bonds. And the Fed will get to keep them if Bank A does not follow through on its promise to repurchase the bonds the next day. Thus, the entire repo process of a sale of bonds followed by a repurchase of bonds is equivalent to the Fed loaning \$10 million to Bank A in exchange for collateral worth \$10 million plus the promise to pay \$50 worth of interest. It is for this reason that repos are usually thought of as collateralized loans rather than as two successive asset transactions.

A reverse repo (“reverse repurchase agreement”) switches the roles of the Fed and the bank. The Fed sells bonds to the bank with the promise to buy them back the next day. The bank holds the bonds as collateral. And the bank will get to keep the collateral if the Fed does not honor its promise to repurchase the bonds the next day.

the money supply). Repos increase the money supply while reverse repos decrease the money supply.

The Reserve Ratio

The Fed also can manipulate the **reserve ratio** in order to influence the ability of commercial banks to lend. Suppose a commercial bank’s balance sheet shows that reserves are \$5,000 and checkable deposits are \$20,000. If the legal reserve ratio is 20 percent (row 2, Table 36.2), the bank’s required reserves are \$4,000. Since actual reserves are \$5,000,

the excess reserves of this bank are \$1,000. On the basis of \$1,000 of excess reserves, this one bank can lend \$1,000; however, the banking system as a whole can create a maximum of \$5,000 of new checkable-deposit money by lending (column 7).

Raising the Reserve Ratio Now, what if the Fed raised the reserve ratio from 20 to 25 percent? (See row 3.) Required reserves would jump from \$4,000 to \$5,000, shrinking excess reserves from \$1,000 to zero. Raising the reserve ratio increases the amount of required reserves banks must keep. As a consequence, either banks lose excess reserves, diminishing their ability to create money by lending, or they find their reserves deficient and are forced to contract checkable deposits and therefore the money supply. In the example in Table 36.2, excess reserves are transformed into required reserves, and the money-creating potential of our single bank is reduced from \$1,000 to zero (column 6). Moreover, the banking system’s money-creating capacity declines from \$5,000 to zero (column 7).

What if the Fed increases the reserve requirement to 30 percent? (See row 4.) The commercial bank, to protect itself against the prospect of failing to meet this requirement, would be forced to lower its checkable deposits and at the same time increase its reserves. To reduce its checkable deposits, the bank could let outstanding loans mature and be repaid without extending new credit. To increase reserves, the bank might sell some of its bonds, adding the proceeds to its reserves. Both actions would reduce the supply of money.

Lowering the Reserve Ratio What would happen if the Fed lowered the reserve ratio from the original 20 percent to 10 percent? (See row 1.) In this case, required reserves would decline from \$4,000 to \$2,000, and excess reserves would jump from \$1,000 to \$3,000. The single bank’s lending (money-creating) ability would increase from \$1,000 to \$3,000 (column 6), and the banking system’s money-creating potential would expand from \$5,000 to \$30,000 (column 7). Lowering the reserve ratio transforms required reserves into excess reserves and enhances the ability of banks to create new money by lending.

The examples in Table 36.2 show that a change in the reserve ratio affects the money-creating ability of the *banking system* in two ways:

- It changes the amount of excess reserves.
- It changes the size of the monetary multiplier.

For example, when the legal reserve ratio is raised from 10 to 20 percent, excess reserves are reduced from \$3,000 to \$1,000 and the checkable-deposit multiplier is reduced from 10 to 5. The money-creating potential of the banking system declines from \$30,000 ($= \$3,000 \times 10$) to \$5,000 ($= \$1,000 \times 5$). Raising the reserve ratio forces banks to reduce the amount of checkable deposits they create through lending.

The Discount Rate

One of the functions of a central bank is to be a “lender of last resort.” Occasionally, commercial banks have unexpected and immediate needs for additional funds. In such cases, each Federal Reserve Bank will make short-term loans to commercial banks in its district.

When a commercial bank borrows, it gives the Federal Reserve Bank a promissory note (IOU) drawn against itself and secured by acceptable collateral—typically U.S. government securities. Just as commercial banks charge interest on the loans they make to their clients, so too Federal Reserve Banks charge interest on loans they grant to commercial banks. The interest rate they charge is called the **discount rate**.

As a claim against the commercial bank, the borrowing bank’s promissory note is an asset to the lending Federal Reserve Bank and appears on its balance sheet as “Loans to commercial banks.” To the commercial bank, the IOU is a liability, appearing as “Loans from the Federal Reserve Banks” on the commercial bank’s balance sheet. [See the two (a) entries on the balance sheets that follow.]

+ Loans to commercial banks (a)	+ Reserves of commercial banks (b)
	
Commercial Banks	
Assets	Liabilities and net worth
+ Reserves (b)	+ Loans from the Federal Reserve Banks (a)

In providing the loan, the Federal Reserve Bank increases the reserves of the borrowing commercial bank. Since no required reserves need be kept against loans from Federal Reserve Banks, all new reserves acquired by borrowing from Federal Reserve Banks are excess reserves. [These changes are reflected in the two (b) entries on the balance sheets.]

In short, borrowing from the Federal Reserve Banks by commercial banks increases the reserves of the commercial banks and enhances their ability to extend credit.

The Fed has the power to set the discount rate at which commercial banks borrow from Federal Reserve Banks. From the commercial banks’ point of view, the discount rate is a cost of acquiring reserves. A lowering of the discount rate encourages commercial banks to obtain additional reserves by borrowing from Federal Reserve Banks. When the commercial banks lend new reserves, the money supply increases.

An increase in the discount rate discourages commercial banks from obtaining additional reserves through borrowing from the Federal Reserve Banks. So the Fed may raise the discount rate when it wants to restrict the money supply.

Interest on Reserves

In 2008, federal law was changed so that the Federal Reserve could for the first time pay banks interest on reserves held at the Fed. Before that time, any reserves held on deposit at the Federal Reserve were paid zero interest. Thus, before 2008, banks had an incentive to keep their reserves as small as possible because any money kept on reserve at the Fed was money earning a zero percent rate of return.

The new law allowed the Fed to set separate rates for required reserves and excess reserves. These are known, respectively, as interest on required reserves (IORR) and **interest on excess reserves (IOER)**. In practice, however, the IORR rate and the IOER rate have been set at equal values, first at 0.25 percent per year from 2008 through December 2015, and then at 0.50 percent per year starting in December 2015.

The Fed’s newfound ability to pay interest on excess reserves provided the Fed with a fourth policy tool by which it

can implement monetary policy and either increase or decrease the amount of monetary stimulus in the economy. As an example, suppose that the Fed wishes to *reduce* the amount of bank lending and, consequently, the amount of money circulating in the economy. It can do so by increasing the rate of interest that it pays on excess reserves held at the Fed. The higher that interest rate, the more of an incentive banks will have to reduce their risky commercial lending for car, mortgage, and business loans in order to instead increase the reserves that they hold at the Fed and thereby earn the risk-free interest rate that the Fed is paying on reserves.

By contrast, if the Fed wishes to *increase* the amount of money that banks lend into the economy, the Fed can lower the interest rate that it pays on excess reserves. The lower rate will make it less attractive for banks to keep reserves, and, consequently, banks will be incentivized to increase consumer and commercial lending and thereby stimulate the economy.

For almost all of 2015, the rate of interest on excess reserves was 0.25 percent per year. Given that banks held about \$2.5 trillion in excess reserves at the Fed that year, the Fed paid a total of about \$6.25 billion (= 0.0025 times \$2.5 trillion) in interest payments to banks for excess reserves held at the Fed in 2015.

Relative Importance

All four of the Fed's instruments of monetary control are useful in particular economic circumstances, but open-market operations are clearly the most important of the four tools over the course of the business cycle. The buying, selling, or pledging as collateral of securities in the open market has the advantage of flexibility—government securities can be purchased, sold, or collateralized daily in large or small amounts—and the impact on bank reserves is prompt. And, compared with reserve-requirement changes, open-market operations work subtly and less directly. Furthermore, the ability of the Federal Reserve Banks to affect commercial bank reserves through open-market bond transactions is virtually unquestionable. The Federal Reserve Banks have very large holdings of government securities (\$2,341 billion in early 2016, for example). The sale of those securities could theoretically reduce commercial bank reserves to zero.

Changing the reserve requirement is a potentially powerful instrument of monetary control, but the Fed has used this technique only sparingly. Normally, it can accomplish its monetary goals more easily through open-market operations. The last change in the reserve requirement was in 1992, when the Fed reduced the requirement from 12 percent to 10 percent. The main purpose was to shore up the profitability of banks and thrifts in the aftermath of the 1990–1991 recession rather than to reduce interest rates by increasing reserves and expanding the money supply.

Until recently, the discount rate was mainly a passive tool of monetary control, with the Fed raising and lowering the rate simply to keep it in line with other interest rates. However, during the financial crisis of 2007–2008, the Fed aggressively lowered the discount rate independently of other interest rates to provide a cheap and plentiful source of reserves to banks whose reserves were being sharply reduced by unexpectedly high default rates on home mortgage loans. Banks borrowed billions at the lower discount rate. This allowed them to meet reserve ratio requirements and thereby preserved their ability to keep extending loans.

QUICK REVIEW 36.3

- ✓ The Fed has four main tools of monetary control, each of which works by changing the amount of reserves in the banking system: (a) conducting open-market operations (the Fed's buying and selling of government bonds to the banks and the public as well as the use of government bonds as collateral for repo and reverse repo loans), (b) changing the reserve ratio (the percentage of commercial bank deposit liabilities required as reserves), (c) changing the discount rate (the interest rate the Federal Reserve Banks charge on loans to banks and thrifts), and (d) changing the interest rate that it pays on reserves held at the Fed.
- ✓ Open-market operations are the Fed's monetary control mechanism of choice for routine increases or decreases in bank reserves over the business cycle; in contrast, changes in reserve requirements and aggressive changes in discount rates or interest on reserves are used only in special situations.

Targeting the Federal Funds Rate

L036.4 Describe the federal funds rate and how the Fed directly influences it.

The Federal Reserve focuses monetary policy on the federal funds rate, which is the short-term interest rate that the Fed can most directly influence. From the previous chapter, you know that the federal funds rate is the rate of interest that banks pay to borrow excess bank reserves overnight from another financial institution. Recall that the Federal Reserve requires banks (and thrifts) to deposit in their regional Federal Reserve Bank a certain percentage of their checkable deposits as reserves. At the end of any business day, some banks may have reserve deficiencies (fewer reserves than required). The Fed allows any such deficiency to be cured through overnight borrowing. Any bank that is deficient in reserves can borrow the amount by which it is deficient from other financial institutions that happen to have excess amounts of reserves.

Before the financial crisis of 2007–2008, excess reserves held overnight at the Federal Reserve earned zero percent

interest. By contrast, banks with excess reserves could obtain a positive interest rate by making overnight loans to banks that had reserve deficiencies. The transactions took place in the federal funds market and an equilibrium interest rate—the **federal funds rate**—was determined by the demand and supply for reserves. (The reserves being lent and borrowed overnight were called “federal funds” because they were funds that were required by the Federal Reserve to meet reserve requirements.)

Before the financial crisis, the Federal Reserve adjusted monetary policy by manipulating the supply of reserves that were offered in the federal funds market. As explained earlier, the Fed could increase or decrease the overall amount of reserves in the banking system by buying and selling government bonds in open-market operations. These changes in the total amount of reserves held by banks in turn affected the amount of excess reserves that banks were willing to supply in the federal funds market—and thus the equilibrium federal funds rate. Under that system, the Federal Open Market Committee (FOMC) met regularly to set a target value (such as 3.75 percent) for the federal funds rate. The trading desk at the New York Fed would then undertake whatever open-market operations were necessary to achieve and maintain the target rate.

The system had to be adjusted in 2008, during the crisis. The FOMC has continued to meet regularly to choose a target for the federal funds rate. But the target has been a range (such as 0.25 percent to 0.50 percent) rather than a value (such as 3.75 percent).

The setting of a target range rather than a target value was a consequence of policy actions that the Fed pursued to contain the mortgage debt crisis of 2008. The Fed purchased so many bonds from banks through open-market operations that nearly every bank in the country ended up with a huge amount of excess reserves. Systemwide, the total amount of excess reserves skyrocketed from \$1.9 billion in August 2008 to \$796.8 billion in January 2009 before continuing to grow steadily over the following years. By early 2016, the U.S. banking system had \$2,267 billion in excess reserves.

This massive increase in excess reserves meant that there were hardly ever any instances where a bank needed to borrow excess reserves overnight in the federal funds market. That lack of demand coupled with the massive increase in the supply of excess reserves had two significant effects:

- The federal funds rate (the equilibrium price of borrowing money in the federal funds market) plunged to nearly zero due to high supply coupled with low demand.
- The number of bank-to-bank transactions in the federal funds market collapsed because there were hardly any instances in which a bank found itself deficient in reserves.

In addition, the massive amount of excess reserves in the banking system meant that the Fed could no longer expect to affect the federal funds rate by using open-market operations to alter the overall amount of excess reserves in the banking system. A \$50 billion or even a \$100 billion change in the overall amount of excess reserves wouldn’t matter when compared to the existing stockpile of \$2,267 billion in excess reserves. The total amount of excess reserves would still be so large that the federal funds rate would remain stuck stubbornly near zero.

That situation forced the Fed to conduct monetary policy very differently after the mortgage debt crisis as compared with before the mortgage debt crisis. In particular, the Fed had to figure out how to conduct monetary policy when the federal funds rate was stuck near zero. To gain a strong understanding of what the Fed came up with, let’s compare how the Fed conducted expansionary and restrictive monetary policy before 2008 versus after 2008.

Expansionary Monetary Policy

Suppose that the economy faces a recession and rising unemployment. How will the Fed respond? It will initiate **expansionary monetary policy** (or “easy money policy”) to increase the supply of credit in the economy and, hopefully, aggregate demand and real output, too.

Expansionary Monetary Policy before the Mortgage Debt Crisis

Before the mortgage debt crisis, excess reserves were low in the banking system and the federal funds rate tended to be in the 3 to 10 percent range. The low volume of excess reserves implied that the Fed could manipulate interest rates by altering bank reserves, while the fact that the federal funds rate was 3 percent or higher meant that the Fed always had room to maneuver short-term interest rates lower to stimulate the economy. The Fed also paid zero interest on excess reserves before the crisis, thereby giving banks an incentive to always try to lend out their excess reserves. Earning a 3 percent or higher federal funds rate by lending excess reserves was better than earning a zero percent return by leaving those reserves on deposit at the Fed.

Given that situation, the Fed’s approach to expansionary monetary policy involved lowering the federal funds rate to boost borrowing and spending (and thereby increase aggregate demand and expand real output). The Fed would initiate an expansionary monetary policy by setting a lower target for the federal funds rate. It would then have three options for reducing the interest rate. The Fed could lower the reserve requirement, lower the discount rate, or use open-market operations to alter the amount of reserves in the banking system. In actual practice, the Fed relied almost exclusively on open-market operations to buy bonds and thereby increase the supply of reserves in the banking system.

FIGURE 36.3 The prime interest rate and the federal funds rate in the United States, 1998–2016. The prime interest rate rises and falls with changes in the federal funds rate.

Source: Federal Reserve Statistical Release, Historical Data, H.15, www.federalreserve.gov.

This increase in reserves had two important effects:

- It increased the supply of excess reserves offered in the federal funds market, thereby lowering the federal funds rate.
- It initiated a multiple expansion of the nation's money supply. Given the demand for money, the larger supply of money would stimulate aggregate demand and real output by putting downward pressure on other interest rates.

One such rate is the **prime interest rate**—the benchmark interest rate used by banks as a reference point for a wide range of interest rates charged on loans to businesses and individuals. The prime interest rate is higher than the federal funds rate because the prime rate involves longer, riskier loans than the overnight loans extended between banks in the federal funds market.

The federal funds rate and the prime interest rate closely track one another, as is evident in Figure 36.3. Also evident is the plunge in both the federal funds rate and the prime rate during the height of the mortgage debt crisis in 2008.

Expansionary Monetary Policy after the Mortgage Debt Crisis The massive increase in excess reserves that took place during the mortgage debt crisis forced the Fed to conduct expansionary monetary policy in a different way.

The post-crisis Fed had two problems when it came to expansionary monetary policy:

- Open-market operations had become ineffective in moving the federal funds rate because even billion-dollar purchases and sales of bonds in the open market left a massive oversupply of excess reserves—and thus a federal funds rate stuck near zero.
- The **zero lower bound problem**, under which a central bank is constrained in its ability to stimulate the economy through lower interest rates because interest rates less than zero (that is, negative interest rates) encourage consumers to withdraw money from banks, thereby reducing the lending capacity of the banking system.

To understand the second problem, suppose that interest rates were forced into negative territory by the Fed. Many people would not want to leave their money in checking accounts because doing so would mean that their balances would shrink over time (rather than grow over time, as they do when interest rates are positive). Thus, any central bank that attempted to impose negative nominal interest rates would see deposits withdrawn from banks. That could be economically catastrophic because the withdrawals would imply that banks would have less money to lend out to consumers and entrepreneurs. The monetary multiplier of Chapter 35 would work in reverse, and the supply of lending

and credit in the economy would decrease precipitously, thereby negatively affecting aggregate demand.

The Fed's response to the zero lower bound problem was **quantitative easing**, or QE. In terms of mechanics, quantitative easing looks exactly like the open-market purchases of bonds that the Fed made before 2008 to lower the federal funds rate. But the Fed's goal when pursuing QE starting in 2008 was not to use open market purchases to lower the federal funds rate (because lowering it when it was already near zero might have caused negative interest rates and a rush to withdraw checking deposits in favor of cash). Rather, the Fed's goal when pursuing QE after 2008 was to buy bonds solely with the intention of increasing the quantity of reserves in the banking system. Interest rates would remain where they were—low but positive—but the larger quantity of excess reserves would hopefully spur banks to lend more and thereby stimulate aggregate demand.

Another difference between QE and regular open-market operations is that QE can involve the purchase of not only U.S. government bonds but also debt issued by U.S. government agencies or government-backed corporations (which are known as government-sponsored entities, or GSEs).

The first round of quantitative easing began in March 2009 and involved the Fed purchasing \$1.75 trillion worth of bonds. The bonds consisted of \$300 billion worth of Treasury bonds and \$1.45 trillion worth of bonds issued by either U.S. government agencies or the two GSE mortgage lenders, Freddie Mac and Fannie Mae. The second round of quantitative easing (“QE2”) began in November 2010 and involved the Fed purchasing \$600 billion of U.S. Treasury bonds. A third and final round (“QE3”) ran from 2012 to 2014 and involved the purchase of an additional \$1.6 trillion worth of securities. Quantitative easing was the Fed's strategy for expansionary monetary policy in a world already awash with excess reserves.

QUICK REVIEW 36.4

- ✓ The federal funds rate is the overnight interest rate at which banks can borrow excess reserves from one another.
- ✓ Policy actions taken by the Fed in response to the mortgage debt crisis resulted in a massive increase in excess reserves, a federal funds rate near zero, and much less activity in the federal funds market.
- ✓ Expansionary monetary policy before 2008 involved the Fed lowering the target federal funds rate and then using open-market operations to buy bonds as necessary to adjust bank reserves to hit the target.
- ✓ Expansionary monetary policy after 2008 consisted of quantitative easing (QE), or massive open-market bond purchases undertaken to increase bank reserves. The Fed kept the federal funds rate low but positive during QE to avoid the zero lower bound problem.

Restrictive Monetary Policy

Suppose that the economy is overheating and inflation is rising. How will the Fed respond? It will initiate a **restrictive monetary policy** (or “tight money policy”) designed to reduce aggregate demand and lower the rate of inflation.

Restrictive Monetary Policy after the Mortgage Debt Crisis

The mortgage debt crisis and the Great Recession of 2007–2009 were so severe that the Fed continued with expansionary monetary policy through the end of 2015, at which point it announced how it would attempt to “normalize” monetary policy by returning short-term interest rates to their historically normal range of 3 percent or higher. The plan also laid out how the Fed could engage in restrictive monetary policy in the face of massive amounts of excess reserves and a federal funds market that continued to be little used.

The Fed's normalization plan had two prongs. The first was to utilize the fact that starting in 2008 the Fed had begun paying interest on excess reserves (IOER) on any excess reserve balances held by member banks. The IOER rate was set at 0.25 percent in 2008 and was unchanged until the end of 2015, when it was raised to 0.50 percent.

The normalization process would involve raising the IOER rate even further in order to get banks to raise other interest rates. To see why raising the IOER rate could be expected to cause other interest rates to rise, suppose that banks could get an IOER of 1 percent by parking excess reserves at the Fed. Under that circumstance, they would not want to lend to anybody else at an interest rate lower than 1 percent. After all, why would the banks want to lend to businesses or individuals for less than 1 percent when they could get 1 percent simply by parking excess reserves at the Fed?

The same would be true for higher IOER rates, such as 2 percent or 3 percent. The higher the IOER rate, the higher the opportunity cost of lending to businesses or individuals; the higher the IOER rate, the more banks would charge to lend money. Thus, the Fed concluded that it could use increases in the IOER rate to help normalize interest rates throughout the economy.

The second prong of the normalization process would be to use reverse repos as a way of making sure that the Fed could raise the federal funds rate, too. The problem that the Fed faced was that after 2008 the federal funds market had come to be dominated not by bank-to-bank lending (as was the case before the mortgage debt crisis) but by nonbank-to-bank lending. In particular, many large financial firms that were not banks (such as mutual funds and government-sponsored entities) were lending excess cash (that is, potential bank reserves) to banks in the federal funds market.

The banks were willing to borrow that money at any rate below the IOER rate of 0.25 percent because they could

immediately deposit the borrowed money at the Fed, increase their excess reserves, and earn the IOER rate of 0.25 percent on whatever they had borrowed from the nonbanks. The difference between the lower rate (of, say, 0.14 percent) that banks borrowed at in the federal funds market and the IOER rate of 0.25 percent that they would receive from the Fed would be pure profit.

The underlying problem was that by law the Fed could only pay IOER to banks. It could not pay IOER to nonbank financial firms. That was problematic because if the Fed had had the ability to pay IOER to nonbanks, too, the Fed could have also gotten the nonbanks to want to lend only at rates higher than the IOER rate by simply offering them the IOER rate on any cash that they wished to lend to the Fed. It was only because the Fed was banned from paying IOER to nonbanks that the nonbanks were willing to lend cash to banks in the federal funds market at less than the IOER rate that banks could get from the Fed.

The federal funds rate averaged just 0.12 percent between the summer of 2009 and December 2015. That was less than half of the upper end of the 0 to 0.25 percent target range that the Fed had set for the federal funds rate. The fact that nonbanks could not access the IOER rate meant that they were willing to lend at an average rate of just 0.12 percent in the federal funds market.

That was extremely problematic because it meant that the Fed could not fully control the federal funds rate. If the Fed was going to raise the federal funds rate as part of normalization, it would have to figure out how to deal with nonbank-to-bank lending in the federal funds market. Its proposed solution was to use reserve repo transactions to soak up the money that the nonbanks were lending to banks in the federal funds market. The Fed would perform a reverse repo with nonbanks, thereby effectively borrowing away the cash that the nonbanks would have otherwise lent to banks in the federal funds market. If the Fed did enough reverse repos with nonbanks while it raised the interest rate on excess reserves, it could make sure that the federal funds rate would always rise up all the way to the IOER rate. The Fed could therefore be confident that it could truly control short-term interest rates and thus all of the other interest rates in the economy, too.

The combination of higher IOER and reverse repo transactions could also be used by the Fed to conduct restrictive monetary policy in the post-crisis economy. A higher interest rate on excess reserves coupled with more reverse repo borrowing would reduce the supply of money and credit to the economy, reduce aggregate demand, and lower inflation.

As of 2016, however, there was no need for tight money. The rate of inflation had remained at or below the Fed's target rate of 2 percent from the start of the mortgage debt crisis through 2016. The Fed was still intending to use higher IOER and reverse repos going forward, but its goal was to use them

in moderation, reducing the money supply by just enough to return interest rates to normal levels, but not so much as to slow the growth of real GDP.

QUICK REVIEW 36.5

- ✓ Restrictive monetary policy before 2008 involved the Fed raising the target for the federal funds rate and then using open-market operations to sell bonds as necessary to adjust bank reserves to hit the target.
- ✓ The Fed ended quantitative easing in 2014 and by the end of 2015 felt the economy was strong enough to start normalizing interest rates, raising them up from the low levels they had reached during the mortgage crisis of 2008.
- ✓ The Fed's plan to normalize interest rates involved raising the interest rate that it pays banks on excess reserves (IOER) while simultaneously using reverse repos to raise the federal funds rate.
- ✓ Pursued aggressively, the combination of higher IOER and reverse repos could also be used by the Fed to engage in a restrictive monetary policy in the post-2008 world of massive excess bank reserves.

The Taylor Rule

The proper federal funds target rate (or target range) for a certain period is a matter of policy discretion by the members of the FOMC. At each of their meetings, committee members assess whether the current target for the federal funds rate remains appropriate for achieving the twin goals of low inflation and full employment. If the majority of the FOMC members conclude that a change is needed, the FOMC sets a new target. This new target is established without adhering to any particular “inflationary target” or “monetary policy rule.” Instead, the committee targets the federal funds rate at the level or range most appropriate for the current underlying economic conditions.

A rule of thumb suggested by economist John Taylor, however, roughly matches the actual policy of the Fed over many time periods. This rule of thumb builds on the belief held by many economists that central banks are willing to tolerate a small positive rate of inflation if doing so will help the economy to produce at potential output. The **Taylor rule** assumes that the Fed has a 2 percent “target rate of inflation” that it is willing to tolerate and that the FOMC follows three rules when setting its target for the federal funds rate:

- When real GDP equals potential GDP and inflation is at its target rate of 2 percent, the federal funds target rate should be 4 percent, implying a real federal funds rate of 2 percent (= 4 percent nominal federal funds rate minus 2 percent inflation rate).

- For each 1 percent increase of real GDP above potential GDP, the Fed should raise the real federal funds rate by $\frac{1}{2}$ percentage point.
- For each 1 percent increase in the inflation rate above its 2 percent target rate, the Fed should raise the *real* federal funds rate by $\frac{1}{2}$ percentage point. (Note, though, that in this case each $\frac{1}{2}$ percentage point increase in the real rate will require a 1.5 percentage point increase in the nominal rate to account for the underlying 1 percent increase in the inflation rate.)

The last two rules are applied independently of each other so that if real GDP is above potential output and at the same time inflation is above the 2 percent target rate, the Fed will apply both rules and raise real interest rates in response to both factors. For instance, if real GDP is 1 percent above potential output and inflation is simultaneously 1 percent above the 2 percent target rate, then the Fed will raise the *real* federal funds rate by 1 percentage point ($= \frac{1}{2}$ percentage point for the excessive GDP + $\frac{1}{2}$ percentage point for the excessive inflation).

Also notice that the last two rules are reversed for situations in which real GDP falls below potential GDP or inflation falls below 2 percent. Each 1 percent decline in real GDP below potential GDP or fall in inflation below 2 percent calls for a decline of the real federal funds rate by $\frac{1}{2}$ percentage point.

We emphasize that the Fed has no official allegiance to the Taylor rule. It changes the federal funds rate to any level (or range) that it deems appropriate. During some periods, its policy has diverged significantly from the Taylor rule.

QUICK REVIEW 36.6

- ✓ The Taylor rule is a mathematical formula that stipulates how the Fed should change real interest rates in response to divergences in real GDP from potential GDP and divergences of actual rates of inflation from the Fed's target rate of inflation.
- ✓ The Fed uses its discretion in setting the federal funds target range, but its decisions regarding monetary policy and the target range appear to be broadly consistent with the Taylor rule over many time periods.

Monetary Policy, Real GDP, and the Price Level

L036.5 Identify the mechanisms by which monetary policy affects GDP and the price level.

We have identified and explained the tools of expansionary and contractionary monetary policy. We now want to emphasize how monetary policy affects the economy's levels of investment, aggregate demand, real GDP, and prices.

Cause-Effect Chain

The four diagrams in **Figure 36.4 (Key Graph)** will help you understand how monetary policy works toward achieving its goals.

Market for Money Figure 36.4a represents the market for money, in which the demand curve for money and the supply curve of money are brought together. Recall that the total demand for money is made up of the transactions and asset demands.

This figure also shows three potential money supply curves, S_{m1} , S_{m2} , and S_{m3} . In each case, the money supply is shown as a vertical line representing some fixed amount of money determined by the Fed.

The equilibrium interest rate is the rate at which the amount of money demanded and the amount supplied are equal. With money demand D_m in Figure 36.4a, if the supply of money is \$125 billion (S_{m1}), the equilibrium interest rate is 10 percent. With a money supply of \$150 billion (S_{m2}), the equilibrium interest rate is 8 percent; with a money supply of \$175 billion (S_{m3}), it is 6 percent.

You know from Chapter 30 that the real, not the nominal, rate of interest is critical for investment decisions. So here we assume that Figure 36.4a portrays real interest rates.

Investment These 10, 8, and 6 percent real interest rates are carried rightward to the investment demand curve in Figure 36.4b. This curve shows the inverse relationship between the interest rate—the cost of borrowing to invest—and the amount of investment spending. At the 10 percent interest rate, it will be profitable for the nation's businesses to invest \$15 billion; at 8 percent, \$20 billion; at 6 percent, \$25 billion.

Changes in the interest rate mainly affect the investment component of total spending, although they also affect spending on durable consumer goods (such as autos) that are purchased on credit. The impact of changing interest rates on investment spending is great because of the large cost and long-term nature of capital purchases. Capital equipment, factory buildings, and warehouses are tremendously expensive. In absolute terms, interest charges on funds borrowed for these purchases are considerable.

Similarly, the interest cost on a house purchased on a long-term contract is very large: A $\frac{1}{2}$ -percentage-point change in the interest rate could amount to thousands of dollars in the total cost of buying a home.

In brief, the impact of changing interest rates is mainly on investment (and, through that, on aggregate demand, output, employment, and the price level). Moreover, as Figure 36.4b shows, investment spending varies inversely with the real interest rate.

Equilibrium GDP Figure 36.4c shows the impact of our three real interest rates and corresponding levels of investment spending on aggregate demand. (Ignore Figure 36.4d for the time being. We will return to it shortly.) As noted,

aggregate demand curve AD_1 is associated with the \$15 billion level of investment, AD_2 with investment of \$20 billion, and AD_3 with investment of \$25 billion. That is, investment spending is one of the determinants of aggregate demand. Other things equal, the greater the investment spending, the farther to the right lies the aggregate demand curve.

Suppose the money supply in Figure 36.4a is \$150 billion (S_{m2}), producing an equilibrium interest rate of 8 percent. In Figure 36.4b we see that this 8 percent interest rate will bring forth \$20 billion of investment spending. This \$20 billion of investment spending joins with consumption spending, net exports, and government spending to yield aggregate demand curve AD_2 in Figure 36.4c. The equilibrium levels of real output and prices are $Q_f = \$900$ billion and P_2 , as determined by the intersection of AD_2 and the aggregate supply curve AS.

To test your understanding of these relationships, explain why each of the other two levels of money supply in Figure 36.4a results in a different interest rate, level of investment, aggregate demand curve, and equilibrium real output.

Effects of an Expansionary Monetary Policy

Recall that the inflationary ratchet effect discussed in Chapter 32 describes the fact that real-world price levels tend to be downwardly inflexible. Thus, with our economy starting from the initial equilibrium where AD_2 intersects AS, the price level will be downwardly inflexible at P_2 so that aggregate supply will be horizontal to the left of Q_f . This means that if aggregate demand decreases, the economy's equilibrium will move leftward along the dashed horizontal line shown in Figure 36.4c.

Just such a decline would happen if the money supply fell to \$125 billion (S_{m1}), shifting the aggregate demand curve leftward to AD_1 in Figure 36.4c. This results in a real output of \$880 billion, \$20 billion less than the economy's full-employment output level of \$900 billion. The economy will be experiencing recession, a negative GDP gap, and substantial unemployment. The Fed therefore should institute an expansionary monetary policy.

To increase the money supply, the Fed will take some combination of the following actions: (1) buy or initiate repos of government securities from banks and the public in the open market, (2) lower the legal reserve ratio, (3) lower the discount rate, and (4) reduce the interest rate that it pays on reserves. The intended outcome will be an increase in excess reserves in the commercial banking system and a decline in the federal funds rate. Because excess reserves are the basis on which commercial banks and thrifts can earn profit by lending and thus creating checkable-deposit money, the nation's money supply will rise. An increase in the money supply will lower the interest rate, increasing investment, aggregate demand, and equilibrium GDP.

For example, an increase in the money supply from \$125 billion to \$150 billion (S_{m1} to S_{m2}) will reduce the interest rate

from 10 to 8 percent, as indicated in Figure 36.4a, and will boost investment from \$15 billion to \$20 billion, as shown in Figure 36.4b. This \$5 billion increase in investment will shift the aggregate demand curve rightward by more than the increase in investment because of the multiplier effect. If the economy's MPC is 0.75, the multiplier will be 4, meaning that the \$5 billion increase in investment will shift the AD curve rightward by \$20 billion ($= 4 \times \5 billion) at each price level. Specifically, aggregate demand will shift from AD_1 to AD_2 , as shown in Figure 36.4c. This rightward shift in the aggregate demand curve along the dashed horizontal line will eliminate the negative GDP gap by increasing GDP from \$880 billion to the full-employment GDP of $Q_f = \$900$ billion.¹

Column 1 in Table 36.3 summarizes the chain of events associated with an expansionary monetary policy.

¹To keep things simple, we assume that the increase in real GDP does not increase the demand for money. In reality, the transactions demand for money would rise, slightly dampening the decline in the interest rate shown in Figure 36.4a.

KEY GRAPH

FIGURE 36.4 Monetary policy and equilibrium GDP. An expansionary monetary policy that shifts the money supply curve rightward from S_{m1} to S_{m2} in (a) lowers the interest rate from 10 to 8 percent in (b). As a result, investment spending increases from \$15 billion to \$20 billion, shifting the aggregate demand curve rightward from AD_1 to AD_2 in (c) so that real output rises from the recessionary level of \$880 billion to the full employment level $Q_f = \$900$ billion along the horizontal dashed line. In (d), the economy at point *a* has an inflationary output gap of \$10 billion because it is producing at \$910 billion, \$10 billion above potential output. A restrictive monetary policy that shifts the money supply curve leftward from $S_{m3} = \$175$ billion to just \$162.5 billion in (a) will increase the interest rate from 6 percent to 7 percent. Investment spending thus falls by \$2.5 billion from \$25 billion to \$22.5 billion in (b). This initial decline is multiplied by 4 by the multiplier process so that the aggregate demand curve shifts leftward in (d) by \$10 billion from AD_3 to AD_4 , moving the economy along the horizontal dashed line to equilibrium *b*. This returns the economy to full employment output and eliminates the inflationary output gap.

QUICK QUIZ FOR FIGURE 36.4

1. The ultimate objective of an expansionary monetary policy is depicted by:
 - a. a decrease in the money supply from S_{m3} to S_{m2} .
 - b. a reduction of the interest rate from 8 to 6 percent.
 - c. an increase in investment from \$20 billion to \$25 billion.
 - d. an increase in real GDP from Q_1 to Q_f .

Effects of a Restrictive Monetary Policy

Next we consider restrictive monetary policy. To prevent overcrowding, we will use graphs *a*, *b*, and *d* (not *c*) in Figure 36.4 to demonstrate the effects of a restrictive monetary policy on the economy. Figure 36.4d represents exactly the same economy as Figure 36.4c but adds some extra curves that relate only to our explanation of restrictive monetary policy.

To see how restrictive monetary policy works, first consider a situation in which the economy moves from a full-employment equilibrium to operating at more than full employment so that inflation is a problem and restrictive

monetary policy would be appropriate. Assume that the economy begins at the full-employment equilibrium where AD_2 and AS intersect. At this equilibrium, $Q_f = \$900$ billion and the price level is P_2 .

Next, assume that the money supply expands from \$150 billion to \$175 billion (S_{m3}) in Figure 36.4a. This results in an interest rate of 6 percent, investment spending of \$25 billion rather than \$20 billion, and aggregate demand AD_3 . As the AD curve shifts to the right from AD_2 to AD_3 in Figure 36.4d, the economy will move along the upsloping AS curve until it comes to an equilibrium at point *a*, where AD_3 intersects AS. At the new equilibrium, the price level has risen to P_3 and the

2. A successful restrictive monetary policy is evidenced by a shift in the money supply curve from:
 - a. S_{m3} to a point halfway between S_{m2} and S_{m3} , a decrease in investment from \$25 billion to \$22.5 billion, and a decline in aggregate demand from AD_3 to AD_4 .
 - b. S_{m1} to S_{m2} , an increase in investment from \$20 billion to \$25 billion, and an increase in real GDP from Q_1 to Q_f .
 - c. S_{m3} to S_{m2} , a decrease in investment from \$25 billion to \$20 billion, and a decline in the price level from P_3 to P_2 .
 - d. S_{m3} to S_{m2} , a decrease in investment from \$25 billion to \$20 billion, and an increase in aggregate demand from AD_2 to AD_3 .
3. The Federal Reserve could increase the money supply from S_{m1} to S_{m2} by:
 - a. increasing the discount rate.
 - b. reducing taxes.
 - c. buying government securities in the open market.
 - d. increasing the reserve requirement.
4. If the spending-income multiplier is 4 in the economy depicted, an increase in the money supply from \$125 billion to \$150 billion will:
 - a. shift the aggregate demand curve rightward by \$20 billion.
 - b. increase real GDP by \$25 billion.
 - c. increase real GDP by \$100 billion.
 - d. shift the aggregate demand curve leftward by \$5 billion.

Answers: 1d; 2a; 3c; 4a

equilibrium level of real GDP has risen to \$910 billion, indicating an inflationary GDP gap of \$10 billion (= \$910 billion – \$900 billion). Aggregate demand AD_3 is excessive relative to the economy's full-employment level of real output $Q_f = \$900$ billion. To rein in spending, the Fed will institute a restrictive monetary policy.

The Federal Reserve Board will direct Federal Reserve Banks to undertake some combination of the following actions: (1) sell or initiate reverse repos of government securities to banks and the public in the open market, (2) increase the legal reserve ratio, (3) increase the discount rate, and (4) increase the interest rate that it pays on reserves. Banks then will discover that their reserves are

below those required and that the federal funds rate has increased. So they will need to reduce their checkable deposits by refraining from issuing new loans as old loans are paid back. This will shrink the money supply and increase the interest rate. The higher interest rate will discourage investment, lowering aggregate demand and restraining demand-pull inflation.

But the Fed must be careful about just how much to decrease the money supply. The problem is that the inflation ratchet will take effect at the new equilibrium point a , such that prices will be inflexible at price level P_3 . As a result, the dashed horizontal line to the left of point a in Figure 36.4d will become relevant. This means that the Fed

cannot simply lower the money supply to S_{m2} in Figure 36.4a. If it were to do that, investment demand would fall to \$20 billion in Figure 36.4b, and the AD curve would shift to the left from AD_3 back to AD_2 . But because of inflexible prices, the economy's equilibrium would move to point c , where AD_2 intersects the horizontal dashed line to the left of point a . This would put the economy into a recession, with equilibrium output below the full-employment output level of $Q_f = \$900$ billion.

What the Fed needs to do to achieve full employment is to move the AD curve back only from AD_3 to AD_4 so that the economy will come to equilibrium at point b . This will require a \$10 billion decrease in aggregate demand so that equilibrium output falls from \$910 billion at point a to $Q_f = \$900$ billion at point b . The Fed can achieve this shift by setting the supply of money in Figure 36.4a at \$162.5 billion. To see how this works, draw in a vertical money supply curve in Figure 36.4a at \$162.5 billion and label it as S_{m4} . It will be exactly halfway between money supply curves S_{m2} and S_{m3} . Notice that the intersection of S_{m4} with the money demand curve D_m will result in an interest rate of 7 percent. In Figure 36.4b, this interest rate of 7 percent will result in investment spending of \$22.5 billion (halfway between \$20 billion and \$25 billion). Thus, by setting the money supply at \$162.5 billion, the Fed can reduce investment spending by \$2.5 billion, lowering it from the \$25 billion associated with AD_3 down to only \$22.5 billion. This decline in investment spending will initially shift the AD curve only \$2.5 billion to the left of AD_3 . But then the multiplier process will work its magic. Since the multiplier is 4 in our model, the AD curve will end up moving by a full \$10 billion ($= 4 \times \2.5 billion) to the left, to AD_4 . This shift will move the economy to equilibrium b , returning output to the full employment level and eliminating the inflationary GDP gap.²

Column 2 in Table 36.3 summarizes the cause-effect chain of a tight money policy.

QUICK REVIEW 36.7

- ✓ The Fed is engaging in an expansionary monetary policy when it increases the money supply to reduce interest rates and increase investment spending and real GDP.
- ✓ The Fed is engaging in a restrictive monetary policy when it reduces the money supply to increase interest rates and reduce investment spending and inflation.

²Again, we assume for simplicity that the decrease in nominal GDP does not feed back to reduce the demand for money and thus the interest rate. In reality, this would occur, slightly dampening the increase in the interest rate shown in Figure 36.4a.

Monetary Policy: Evaluation and Issues

L036.6 Explain the effectiveness of monetary policy and its shortcomings.

Monetary policy has become the dominant component of U.S. national stabilization policy. It has two key advantages over fiscal policy:

- Speed and flexibility.
- Isolation from political pressure.

Compared with fiscal policy, monetary policy can be quickly altered. Recall that congressional deliberations may delay the application of fiscal policy for months. In contrast, the Fed can buy or sell securities from day to day and thus affect the money supply and interest rates almost immediately.

Also, because members of the Fed's Board of Governors are appointed and serve 14-year terms, they are relatively isolated from lobbying and need not worry about retaining their popularity with voters. Thus, the Board, more readily than Congress, can engage in politically unpopular policies (higher interest rates) that may be necessary for the long-term health of the economy. Moreover, monetary policy is a subtler and more politically neutral measure than fiscal policy. Changes in government spending directly affect the allocation of resources, and changes in taxes can have extensive political ramifications. Because monetary policy works more subtly, it is more politically palatable.

Recent U.S. Monetary Policy

The Fed has been highly active in its use of monetary policy in recent decades.

The 2007–2009 Recession The mortgage default crisis (discussed in Chapter 34) began during the late summer of 2007 and posed a grave threat to the financial system and the economy. In response, the Fed took several actions. In August it lowered the discount rate by half a percentage point. Then, between September 2007 and April 2008, it lowered the target for the federal funds rate from 5.25 percent to 2 percent. And as discussed in Chapter 34, the Fed also took a series of extraordinary actions to prevent the failure of key financial firms.

In October 2008, the Fed first reduced the federal funds target rate to 1.5 percent and then later that same month to 1 percent. In December 2008, the Fed lowered it further to a targeted range of 0 percent to 0.25 percent. That near-zero targeted range was by far the lowest in history. All these monetary actions and lender-of-last-resort

functions helped to stabilize the banking sector and keep credit flowing—thereby offsetting at least some of the damage done by the financial crisis.

The decline in the federal funds rate to near zero during the financial and economic crisis dropped the prime interest rate (review Figure 36.4). In December 2007, the prime interest rate stood at 7.3 percent. By January 2009, it had declined to 3.25 percent, where it remained through December 2015.

The Federal Reserve is lauded by most observers for its quick and innovative actions during the financial crisis and severe recession. Nevertheless, some economists contend that the Fed contributed to the financial crisis by holding the federal funds interest rate too low for too long during the recovery from the 2001 recession. These critics say that the artificially low interest rates made mortgage and other loans too inexpensive and therefore contributed to the borrowing frenzy by homeowners and other financial investors. Other economists counter that the low mortgage interest rates resulted from huge inflows of savings from abroad to a wide variety of U.S. financial markets.

After the Great Recession The U.S. economy recovered very slowly from the Great Recession of 2007–2009, especially in terms of employment. The Federal Reserve understood the depth of the economy’s problems early on and responded with a series of innovative monetary policy initiatives designed to stimulate GDP and employment growth.

The Fed began by moving toward a **zero interest rate policy**, or **ZIRP**, in December 2008. Under ZIRP, the Fed aimed to keep short-term interest rates near zero to stimulate the economy. The federal funds rate was lowered rapidly, as can be seen in Figure 36.4, and the Fed also acted as a lender of last resort, purchasing securities from banks and other financial institutions in order to provide them with liquidity and the ability to make timely debt payments.

Many of the Fed’s lender-of-last-resort securities purchases were from banks. The purchases were so massive that the banking system’s excess reserves skyrocketed. This left the Fed in a quandary. It wanted to continue to stimulate the economy, but traditional monetary policy was made difficult by the already-low interest rates and the difficulties associated with the zero lower bound problem. The Fed did not want to risk negative interest rates, so reductions in the the federal funds rate (which low but positive) were off the table. Another method had to be found to stimulate the economy.

The Fed’s solution was *quantitative easing*, or QE. Under QE, the Fed bought bonds solely with the intention of increasing the quantity of reserves in the banking system.

Interest rates remained at the same (low but positive) levels to avoid the zero lower bound problem, but with excess reserves increasing thanks to QE, banks would hopefully lend more and thereby stimulate the economy.

The first round of QE began in March 2009, the second in November 2010, and the third and final round in 2012. They involved securities purchases of, respectively, \$1.75 trillion, \$600 billion, and \$1.61 trillion.

The economy mended slowly, but by the end of 2015, the Fed felt that various economic indicators were signaling that monetary stimulus could end. The unemployment rate, in particular, had fallen back to just 5 percent after reaching 10 percent in 2009. The FOMC decided that the Fed could abandon ZIRP while attempting to raise interest rates back up to normal levels.

The Fed’s first step was to raise the IOER rate from 0.25 percent to 0.50 percent in December 2015 while simultaneously raising the target range for the federal funds rate from 0 to 0.25 percent up to 0.25 to 0.50 percent. At the same time, the Fed began reverse repo transactions with non-banks to push the equilibrium federal funds rate up toward the top end of the 0.25 percent to 0.50 percent target range. By doing so, the Fed could guarantee that the short-term interest rate facing nonbanks would be nearly the same as the 0.50 IOER rate facing banks. In this way, the Fed could ensure that it had control over short-term interest rates throughout the financial sector and not just with banks. That would preserve the Fed’s ability to tighten or loosen credit throughout the economy going forward.

Problems and Complications

Despite its recent successes in the United States, monetary policy has certain limitations and faces actual-economy complications.

Lags Recall that fiscal policy is hindered by three delays, or lags—a recognition lag, an administrative lag, and an operational lag. Monetary policy also faces a recognition lag and an operational lag, but because the Fed can decide and implement policy changes within days, it avoids the long administrative lag that hinders fiscal policy.

A recognition lag affects monetary policy because normal monthly variations in economic activity and the price level mean that the Fed may not be able to quickly recognize when the economy is truly starting to recede or when inflation is really starting to rise. Once the Fed acts, an operational lag of 3 to 6 months affects monetary policy because that much time is typically required for interest-rate changes to have their full impacts on investment, aggregate demand, real GDP, and the price level. These two lags complicate the timing of monetary policy.

Less Than Zero

Fearing the Zero Lower Bound, Central Banks Set Low but Positive Interest Rates after the Mortgage Debt Crisis. But What if Negative Rates Are Actually an Option?

As of mid-2016, the Fed planned to raise short-term interest rates back up to historically normal levels. Doing so would give the Fed a policy cushion because a normalized federal funds rate of, say, 5 percent would give the Fed the wiggle room it would need to cut interest rates back down toward zero if stimulus were needed to fight a future recession. But as of mid-2016, the federal funds rate remained near zero, and the Fed had to wonder what it might do to stimulate the economy if another recession started before rates had been raised back up to normal levels.

One option would be to try another round of quantitative easing, with interest rates kept low but positive. An entirely different option had, however, already been taken by the European Central Bank (ECB) on behalf of the 19 countries that use the euro as their currency. In 2014, the ECB dared to plunge below the zero lower

bound. By March 2016, the ECB had lowered its version of the federal funds rate down to *negative* 0.4 percent. Similar overnight lending rates in Denmark and Switzerland stood at -0.65 percent and -0.75 percent, respectively. Like a rare black swan plunging its head below the surface of a pond, European central banks had plunged decisively into negative territory.

The ECB had set negative rates in an attempt to force banks to lend more. After all, if banks were set to lose 0.40 percent per year on any unloaned excess reserves, they would be better off lending them out at any interest rate greater than -0.40 percent, including negative rates such as -0.35 percent and -0.12 percent.

Strangely, that is what began to happen. In some countries, home mortgage rates turned negative, so that people were getting paid to borrow money to buy a house. Instead of the borrower

Cyclical Asymmetry and the Liquidity Trap Monetary policy may be highly effective in slowing expansions and controlling inflation but may be much less reliable in pushing the economy from a severe recession. Economists say that monetary policy may suffer from **cyclical asymmetry**. The metaphor of “pushing on a string” is often invoked to capture this problem. Imagine the Fed standing on the left-hand side of Figure 36.4d, holding one end of a “monetary-policy string.” And imagine that the other end of the monetary-policy string is tied to the AD curve. Because the string would go taut if pulled on, monetary policy may be useful in *pulling* aggregate demand to the left. But because the string would go limp if pushed on, monetary policy will be rather ineffective at *pushing* aggregate demand to the right.

The reason for this asymmetry has to do with the asymmetric way in which people may act in response to changes in bank reserves. If pursued vigorously, a restrictive monetary policy can deplete commercial banking reserves to the point where banks are forced to reduce the volume of loans. That means a contraction of the money supply, higher interest rates, and reduced aggregate demand. The Fed can absorb sufficient reserves and eventually achieve its goal.

But the Fed cannot be certain of achieving its goal when it adds reserves to the banking system because of the so-called **liquidity trap**, in which adding more liquidity to banks has little or no additional positive effect on lending, borrowing, investment, or aggregate demand. For example, during the recent recession, the Fed created billions of dollars of excess reserves that drove down the federal funds rate to as low as 0.2 percent. The prime interest rate fell from 7.3 percent (December 2007) to 3.25 percent (March 2009). Nevertheless, lending by banks stalled throughout the first 15 months of the recession and remained weak even after the Fed implemented ZIRP and QE, over the following five years. The banks were fearful that the loans they would make to households, businesses, and other financial institutions would not be paid back. Consequently, they were content to hold reserves at the Federal Reserve Banks.

To switch analogies, an expansionary monetary policy can suffer from a “you can lead a horse to water, but you can’t make it drink” problem. The Fed can create excess reserves, but it cannot guarantee that the banks will actually make additional loans and thus promote spending. If commercial banks seek liquidity and are unwilling to lend, the efforts of the Fed will be of little avail. Similarly,

mailing in a mortgage payment each month, the bank mailed the borrower a check for the negative interest they were earning by borrowing.

Checking and savings account rates also turned negative. As they did, the incentives generated by negative interest rates began to affect behavior. People began to withdraw money from banks, turning electronic bank balances into physical cash. They did so because they understood opportunity cost. Why get a negative rate on a bank balance when you could hold cash and lose nothing?

With people withdrawing money in the face of negative rates, the various European central banks were in a pickle. Lower (i.e., even more negative) rates would spur banks to lend more of their excess reserves. But the banks would have less reserves to lend out as people withdrew bank balances in favor of cash.

Macroeconomists who had previously worried about the zero lower bound began to speculate about the existence of a “negative lower bound.” They conjectured that there was likely a negative rate (perhaps -3.0 percent) beyond which any further cuts in interest rates would be counterproductive and fail to stimulate the economy. They reasoned that below the negative lower bound, withdrawals from the banking system would reduce the total amount lent out by banks by more than negative rates helped to increase lending. Negative rates might be stimulatory for a while, but only with diminishing effectiveness and only up until the negative lower bound was reached.

households and businesses can frustrate the intentions of the Fed by not borrowing excess reserves being made available as loans. And when the Fed buys securities from the public, people may choose to pay off existing loans with the money received, rather than increase their spending on goods and services.

Furthermore, a severe recession may so undermine business confidence that the investment demand curve shifts to the left and overwhelms the lower interest rates associated with an expansionary monetary policy. That is what happened in the most recent recession. Although the Fed drove the real interest rate down to zero percent, investment spending remained low and the economy remained mired in recession. The recent U.S. experience reminds us that active monetary policy certainly is not a cure-all for the business cycle. Under some circumstances, monetary policy may be like “pushing on a string.”

The liquidity trap that occurred during the severe recession was a primary reason why public policy in the United States turned so significantly and forcefully toward fiscal policy in 2009. Recall our discussion of the American Recovery and Reinvestment Act of 2009, which authorized the infusion of \$787 billion of new tax cuts and government spending in 2009 and 2010.

But where is the negative lower bound? How far can central banks go below zero before lower interest rates lose the power to stimulate? One hint comes from looking at the convenience of electronic payments. Many Europeans these days barely use cash. It is simpler to swipe credit and debit cards or wave one’s phone to complete a purchase. So a great deal of the reason people leave money in bank accounts is to facilitate electronic transactions. If they switched to cash, they would lose that convenience.

Thus, one way to estimate a possible value for the zero lower bound would be to ask: “How negative could interest rates go before the loss of purchasing power exceeds the convenience that comes from being able to utilize electronic payments?” For some individuals, the tipping point might be -1.0 percent. For others, it might come at -2.5 or -4.25 percent. But beyond some point, the loss of purchasing power caused by a negative interest rate will loom larger in people’s minds as interest rates decline further into negative territory. The lower the rate, the less people will want to hold electronic bank balances. The lower the rate, the more people will convert electronic bank balances into physical cash. The lower the rate, the smaller excess reserves will be.

The Fed will have to consider those trade-offs if the United States enters a recession before the Fed has had a chance to raise short-term interest rates back up to historical levels. If stimulus proves necessary, will the Fed stick with quantitative easing—or will it dare to follow the ECB into negative territory?

QUICK REVIEW 36.8

- ✓ The Fed aggressively lowered the federal funds interest rate during the severe recession of 2007–2009.
- ✓ To help stimulate the economy after the Great Recession, the Fed implemented the zero interest rate policy (ZIRP) and quantitative easing (QE).
- ✓ The main strengths of monetary policy are (a) speed and flexibility and (b) political acceptability; its main weaknesses are (a) time lags and (b) potential ineffectiveness during severe recession.

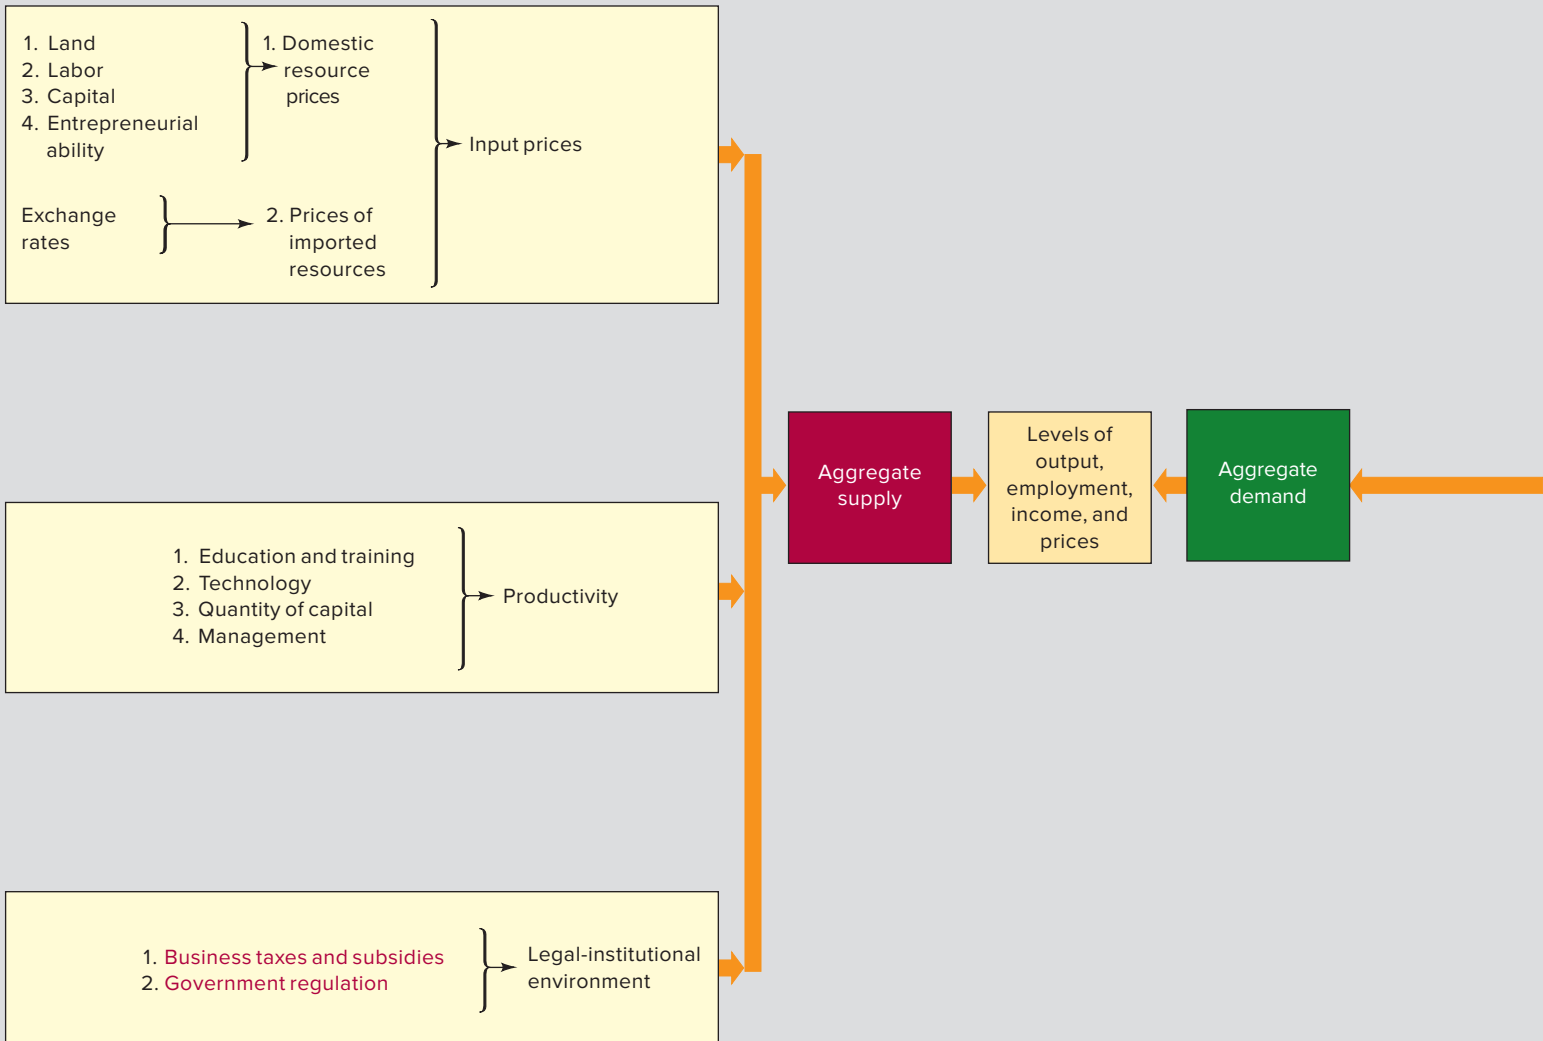

The “Big Picture”

Figure 36.5 (Key Graph) brings together the analytical and policy aspects of macroeconomics discussed in this and the eight preceding chapters. This “big picture” shows how the many concepts and principles discussed relate to one another and how they constitute a coherent theory of the price level and real output in a market economy.

Study this diagram and you will see that the levels of output, employment, income, and prices all result from the interaction of aggregate supply and aggregate demand. The items shown in red relate to public policy.

QUICK QUIZ FOR FIGURE 36.5

- All else equal, an increase in domestic resource availability will:
 - increase input prices, reduce aggregate supply, and increase real output.
 - raise labor productivity, reduce interest rates, and lower the international value of the dollar.
 - increase net exports, increase investment, and reduce aggregate demand.
 - reduce input prices, increase aggregate supply, and increase real output.
- All else equal, an expansionary monetary policy during a recession will:
 - lower the interest rate, increase investment, and reduce net exports.
 - lower the interest rate, increase investment, and increase aggregate demand.
 - increase the interest rate, increase investment, and reduce net exports.
 - reduce productivity, aggregate supply, and real output.

3. A personal income tax cut, combined with a reduction in corporate income and excise taxes, would:
 - a. increase consumption, investment, aggregate demand, and aggregate supply.
 - b. reduce productivity, raise input prices, and reduce aggregate supply.
 - c. increase government spending, reduce net exports, and increase aggregate demand.
 - d. increase the supply of money, reduce interest rates, increase investment, and expand real output.
4. An appreciation of the dollar would:
 - a. reduce the price of imported resources, lower input prices, and increase aggregate supply.
 - b. increase net exports and aggregate demand.
 - c. increase aggregate supply and aggregate demand.
 - d. reduce consumption, investment, net export spending, and government spending.

SUMMARY

L036.1 Discuss how the equilibrium interest rate is determined in the market for money.

The total demand for money consists of the transactions demand for money plus the asset demand for money. The amount of money demanded for transactions varies directly with the nominal GDP; the amount of money demanded as an asset varies inversely with the interest rate. The market for money combines the total demand for money with the money supply to determine equilibrium interest rates.

Interest rates and bond prices are inversely related.

L036.2 Describe the balance sheet of the Federal Reserve and the meaning of its major items.

The consolidated balance sheet of the Federal Reserve System lists the collective assets and liabilities of the 12 Federal Reserve banks. The assets consist largely of Treasury notes, Treasury bills, and Treasury bonds. The major liabilities are reserves of commercial banks, Treasury deposits, and Federal Reserve notes outstanding. The balance sheet is useful in understanding monetary policy because open-market operations increase or decrease the Fed's assets and liabilities.

L036.3 List and explain the goals and tools of monetary policy.

The goal of monetary policy is to help the economy achieve price stability, full employment, and economic growth.

The four main instruments of monetary policy are (a) open-market operations, (b) the reserve ratio, (c) the discount rate, and (d) interest on reserves.

L036.4 Describe the federal funds rate and how the Fed directly influences it.

The federal funds rate is the interest rate that banks charge one another for overnight loans of excess reserves. The prime interest rate is the benchmark rate that banks use as a reference rate for a wide range of interest rates on short-term loans to businesses and individuals.

The Fed adjusts the federal funds rate to a level deemed appropriate for economic conditions. Before the mortgage debt crisis, the Fed would engage in expansionary or restrictive monetary policy by announcing a new target for the federal funds rate and then using open-market operations to buy or sell government bonds in whatever amounts were necessary to achieve the target rate.

This policy no longer worked after the mortgage debt crisis because the banking system had ended up with a massive surplus of excess reserves. That massive surplus forced the federal funds rate to nearly zero, so that the Fed could no longer pursue its traditional stimulatory strategy of lowering interest rates to boost bank

lending. That strategy was now problematic due to the zero lower bound problem and the fact that negative interest rates might reduce rather than increase the total volume of bank lending.

With the Fed unwilling to lower interest rates due to the zero lower bound problem, the Fed left the federal funds rate alone and instead concentrated on a policy of quantitative easing (QE) in which it purchased bonds not to lower interest rates but to increase reserves in the banking system and thereby spur lending and aggregate demand (it being hoped that additional reserves would lead to additional lending).

By late 2015, the Fed felt that the economy was recovering strongly enough to try to begin raising interest rates back up to their pre-crisis levels. The method chosen was to raise the interest rate on excess reserves (IOER) while simultaneously using reverse repo transactions to raise the federal funds rate. While this policy was being pursued in a gradual fashion starting in 2015 as part of the Fed's attempt to slowly normalize interest rates, a more rapid version could be used to reduce lending and thereby engage in a restrictive monetary policy if the economy were to overheat at a later date.

L036.5 Identify the mechanisms by which monetary policy affects GDP and the price level.

Monetary policy affects the economy through a complex cause-effect chain: (a) policy decisions affect commercial bank reserves; (b) changes in reserves affect the money supply; (c) changes in the money supply alter the interest rate; (d) changes in the interest rate affect investment; (e) changes in investment affect aggregate demand; (f) changes in aggregate demand affect the equilibrium real GDP and the price level. Table 36.3 draws together all the basic ideas relevant to the use of monetary policy.

L036.6 Explain the effectiveness of monetary policy and its shortcomings.

The advantages of monetary policy include its flexibility and political acceptability. In recent years, the Fed has used monetary policy to help stabilize the banking sector in the wake of the mortgage debt crisis and to promote recovery from the severe recession of 2007–2009. Today, nearly all economists view monetary policy as a significant stabilization tool.

Monetary policy has two major limitations and potential problems: (a) recognition and operation lags complicate the timing of monetary policy; (b) in a severe recession, the reluctance of banks to lend excess reserves and firms to borrow money to spend on capital goods may contribute to a liquidity trap that limits the effectiveness of an expansionary monetary policy.

DISCUSSION QUESTIONS

1. What is the basic determinant of (a) the transactions demand and (b) the asset demand for money? Explain how these two demands can be combined graphically to determine total money demand. How is the equilibrium interest rate in the money market determined? Use a graph to show the effect of an increase in the total demand for money on the equilibrium interest rate (no change in money supply). Use your general knowledge of equilibrium prices to explain why the previous interest rate is no longer sustainable. **L036.1**
2. What is the basic objective of monetary policy? What are the major strengths of monetary policy? Why is monetary policy easier to conduct than fiscal policy? **L036.3**
3. Distinguish between the federal funds rate and the prime interest rate. Why is one higher than the other? Why do changes in the two rates closely track one another? **L036.4**
4. Distinguish between how the Fed would have to undertake restrictive monetary policy today versus before the mortgage-debt crisis. What actions would it need to take in each case? **L036.4**
5. Suppose that you are a member of the Board of Governors of the Federal Reserve System. The post-2008 economy is experiencing a sharp rise in the inflation rate. What change in the federal funds rate would you recommend? How would your recommended change get accomplished? What impact would the actions have on the lending ability of the banking system, the real interest rate, investment spending, aggregate demand, and inflation? **L036.5**
6. Explain the links between changes in the nation's money supply, the interest rate, investment spending, aggregate demand, real GDP, and the price level. **L036.5**
7. What do economists mean when they say that monetary policy can exhibit cyclical asymmetry? How does the idea of a liquidity trap relate to cyclical asymmetry? Why is this possibility of a liquidity trap significant to policymakers? **L036.6**
8. **LAST WORD** By what chain of causation does the ECB think negative interest rates will stimulate the economy? If the Fed manages to raise interest rates up to historical levels before the next recession, will it have to consider negative interest rates as a first course of action in terms of stimulating the economy? Explain.

REVIEW QUESTIONS

1. When bond prices go up, interest rates go _____. **L036.1**
 - a. Up.
 - b. Down.
 - c. Nowhere.
2. A commercial bank sells a Treasury bond to the Federal Reserve for \$100,000. The money supply: **L036.3**
 - a. Increases by \$100,000.
 - b. Decreases by \$100,000.
 - c. Is unaffected by the transaction.
3. Use commercial bank and Federal Reserve Bank balance sheets to demonstrate the effect of each of the following transactions on commercial bank reserves: **L036.3**
 - a. Federal Reserve Banks purchase securities from banks.
 - b. Commercial banks borrow from Federal Reserve Banks at the discount rate.
 - c. The Fed reduces the reserve ratio.
 - d. Commercial banks increase their reserves after the Fed increases the interest rate that it pays on reserves.
4. A bank currently has \$100,000 in checkable deposits and \$15,000 in actual reserves. If the reserve ratio is 20 percent, the bank has _____ in money-creating potential. If the reserve ratio is 14 percent, the bank has _____ in money-creating potential. **L036.3**
 - a. \$20,000; \$14,000.
 - b. \$3,000; \$2,100.
 - c. -\$5,000; \$1,000.
 - d. \$5,000; \$1,000.
5. A bank borrows \$100,000 from the Fed, leaving a \$100,000 Treasury bond on deposit with the Fed to serve as collateral for the loan. The discount rate that applies to the loan is 4 percent and the Fed is currently mandating a reserve ratio of 10 percent. How much of the \$100,000 borrowed by the bank must it keep as required reserves? **L036.3**
 - a. \$0.
 - b. \$4,000.
 - c. \$10,000.
 - d. \$100,000.
6. Which of the following Fed actions will increase bank lending? **L036.3**
Select one or more answers from the choices shown.
 - a. The Fed raises the discount rate from 5 percent to 6 percent.
 - b. The Fed raises the reserve ratio from 10 percent to 11 percent.
 - c. The Fed initiates reverse repos involving \$10 billion worth of Treasury bonds with nonbank financial firms.
 - d. The Fed lowers the discount rate from 4 percent to 2 percent.

7. If the Federal Reserve wants to increase the federal funds rate using open-market operations, it should _____ bonds to nonbank financial firms. **L036.4**
- Initiate repos of.
 - Initiate reverse repos of.
8. True or False: A liquidity trap occurs when expansionary monetary policy fails to work because an increase in bank reserves by the Fed does not lead to an increase in bank lending. **L036.6**
9. True or False: In the United States, monetary policy has two key advantages over fiscal policy: (1) isolation from political pressure and (2) speed and flexibility. **L036.6**

PROBLEMS

1. Assume that the following data characterize the hypothetical economy of Trance: money supply = \$200 billion; quantity of money demanded for transactions = \$150 billion; quantity of money demanded as an asset = \$10 billion at 12 percent interest, increasing by \$10 billion for each 2-percentage-point fall in the interest rate. **L036.1**
- What is the equilibrium interest rate in Trance?
 - At the equilibrium interest rate, what are the quantity of money supplied, the total quantity of money demanded, the amount of money demanded for transactions, and the amount of money demanded as an asset in Trance?
2. Suppose a bond with no expiration date has a face value of \$10,000 and annually pays a fixed amount of interest of \$800. In the table provided below, calculate and enter either the interest rate that the bond would yield to a bond buyer at each of the bond prices listed or the bond price at each of the interest yields shown. What generalization can be drawn from the completed table? **L036.1**

Bond Price	Interest Yield, %
\$ 8,000	_____
_____	8.9
\$10,000	_____
\$11,000	_____
_____	6.2

3. In the tables that follow you will find consolidated balance sheets for the commercial banking system and the 12 Federal Reserve Banks. Use columns 1 through 3 to indicate how the balance sheets would read after each of transactions a to c is completed. Do not cumulate your answers; that is, analyze each transaction separately, starting in each case from the numbers provided. All accounts are in billions of dollars. **L036.3**

- a. A decline in the discount rate prompts commercial banks to borrow an additional \$1 billion from the Federal Reserve Banks. Show the new balance-sheet numbers in column 1 of each table.
 - b. The Federal Reserve Banks sell \$3 billion in securities to members of the public, who pay for the bonds with checks. Show the new balance-sheet numbers in column 2 of each table.
 - c. The Federal Reserve Banks buy \$2 billion of securities from commercial banks. Show the new balance-sheet numbers in column 3 of each table.
 - d. Now review each of the previous three transactions, asking yourself these three questions: (1) What change, if any, took place in the money supply as a direct and immediate result of each transaction? (2) What increase or decrease in the commercial banks' reserves took place in each transaction? (3) Assuming a reserve ratio of 20 percent, what change in the money-creating potential of the commercial banking system occurred as a result of each transaction?
4. Refer to Table 36.2 and assume that the Fed's reserve ratio is 10 percent and the economy is in a severe recession. Also suppose that the commercial banks are hoarding all excess reserves (not lending them out) because of their fear of loan defaults. Finally, suppose that the Fed is highly concerned that the banks will suddenly lend out these excess reserves and possibly contribute to inflation once the economy begins to recover and confidence is restored. By how many percentage points would the Fed need to increase the reserve ratio to eliminate one-third of the excess reserves? What would be the size of the monetary multiplier before and after the change in the reserve ratio? By how much would the lending potential of the banks decline as a result of the increase in the reserve ratio? **LO36.3**
 5. Suppose that the target range for the federal funds rate is 1.5 to 2.0 percent but that the equilibrium federal funds rate is currently 1.70 percent. Assume that the equilibrium federal funds rate falls (rises) by 1 percent for each \$120 billion in repo (reverse repo) bond transactions the Fed undertakes. If the Fed wishes to raise the equilibrium federal funds rate up to the top end of the target range, will it initiate repos or reverse repos of bonds to nonbank financial firms? How much will it have to repo or reverse repo? **LO36.4**
 6. Suppose that inflation is 2 percent, the federal funds rate is 4 percent, and real GDP falls 2 percent below potential GDP. According to the Taylor rule, in what direction and by how much should the Fed change the real federal funds rate? **LO36.4**
 7. Refer to the table for Moola below to answer the following questions. What is the equilibrium interest rate in Moola? What is the level of investment at the equilibrium interest rate? Is there either a recessionary output gap (negative GDP gap) or an inflationary output gap (positive GDP gap) at the equilibrium interest rate and, if either, what is the amount? Given money demand, by how much would the Moola central bank need to change the money supply to close the output gap? What is the expenditure multiplier in Moola? **LO36.5**

Financial Economics

Learning Objectives

- L037.1** Define *financial economics* and distinguish between economic investment and financial investment.
- L037.2** Explain the time value of money and how compound interest can be used to calculate the present value of any future amount of money.
- L037.3** Identify and distinguish among the most common financial investments: stocks, bonds, and mutual funds.
- L037.4** Relate how percentage rates of return provide a common framework for comparing assets and explain why asset prices and rates of return are inversely related.
- L037.5** Define and utilize the concept of arbitrage.
- L037.6** Describe how the word *risk* is used in financial economics and explain the difference between diversifiable and nondiversifiable risk.
- L037.7** Convey why investment decisions are determined primarily by investment returns and nondiversifiable risk and how investment returns compensate for being patient and for bearing nondiversifiable risk.
- L037.8** Explain how the Security Market Line illustrates the compensation that investors receive for time preference and nondiversifiable risk and why arbitrage will tend to move all assets onto the Security Market Line.

Financial economics studies investor preferences and how they affect the trading and pricing of financial assets like stocks, bonds, and real estate. The two most important investor preferences are a desire for high rates of return and a dislike of risk and uncertainty. This chapter will explain how these preferences interact to produce a strong positive relationship between risk and return: the riskier an investment, the higher its rate of return. This positive relationship compensates investors for bearing risk. And it is enforced by a powerful set of buying and selling

pressures known as arbitrage, which ensures consistency across investments so that assets with identical levels of risk generate identical rates of return. As we will demonstrate, this consistency makes it extremely difficult for anyone to “beat the market” by finding a set of investments that can generate high rates of return at low levels of risk.

Instead, investors are stuck with a trade-off: If they want higher rates of return, they must accept higher levels of risk. On average, higher risk results in higher returns. But it can also result in large losses, as it did for many investors who held risky assets during the financial crisis of 2007–2008.

Financial Investment

L037.1 Define *financial economics* and distinguish between economic investment and financial investment.

Financial economics focuses its attention on the investments that individuals and firms make in the wide variety of assets available to them in our modern economy. But before proceeding, it is important for you to recall the difference between economic investment and financial investment.

Economic investment refers either to paying for *new* additions to the capital stock or *new* replacements for capital stock that has worn out. Thus, *new* factories, houses, retail stores, construction equipment, and wireless networks are all good examples of economic investments. And so are purchases of office computers to replace computers that have become obsolete as well as purchases of new commercial airplanes to replace planes that have served out their useful lives.

In contrast, financial investment is a far broader, much more inclusive concept. It includes economic investment and a whole lot more. **Financial investment** refers to either buying an asset or building an asset in the expectation of financial gain. It does not distinguish between *new* assets and *old* assets. Purchasing an old house or an old factory is just as much a financial investment as purchasing a new house or a new factory. For financial investment, it does not matter if the purchase of an asset adds to the capital stock, replaces the capital stock, or does neither. Investing in old comic books is just as much a financial investment as building a new refinery. Finally, unlike economic investment, financial investment can involve either *financial assets* (such as stocks, bonds, and futures contracts) or *real assets* (such as land, factories, and retail stores).

When bankers, entrepreneurs, corporate executives, retirement planners, and ordinary people use the word *investment*, they almost always mean financial investment. In fact, the ordinary meaning of the word *investment* is financial investment. So for this chapter, we will use the word *investment* in its ordinary sense of “financial investment” rather than in the far narrower sense of “economic investment,” which is used throughout the rest of this book.

Present Value

L037.2 Explain the time value of money and how compound interest can be used to calculate the present value of any future amount of money.

Money has “time value” because current dollars can be converted into a larger amount of future dollars through compound interest. The *time-value of money* is the idea that a specific amount of money is more valuable to a person the sooner it is received, and a person will need to be compensated for waiting to obtain it later. The time-value of money can also be thought of as the opportunity cost of receiving a sum of money later rather than earlier.

The time-value of money underlies one of the most fundamental ideas in financial economics: **present value**, which is the present-day value, or worth, of returns or costs that are expected to arrive in the future. The ability to calculate present values is especially useful when investors wish to determine the proper current price to pay for an asset. In fact, the proper current price for any risk-free investment is the present value of its expected future returns. And while some adjustments have to be made when determining the proper price of a risky investment, the process is entirely based on the logic of present value. So we begin our study of finance by explaining present value and how it can be used to price risk-free assets. Once that is accomplished, we will turn our attention to risk and how the financial markets determine the prices of risky assets by taking into account investor preferences regarding the trade-off between potential return and potential risk.

Compound Interest

The best way to understand present value is by first understanding compound interest. **Compound interest** describes how quickly an investment increases in value when interest is paid, or compounded, not only on the original amount invested but also on all interest payments that have been previously made.

As an example of compound interest in action, consider Table 37.1, which shows the amount of money that \$100 invested today becomes if it increases, or compounds, at an 8 percent annual interest rate, i , for various numbers of years.

TABLE 37.1 Compounding: \$100 at 8 Percent Interest

(1) Years of Compounding	(2) Compounding Computation	(3) Value at Year's End
1	\$100 (1.08)	\$108.00
2	100 (1.08) ²	116.64
3	100 (1.08) ³	125.97
4	100 (1.08) ⁴	136.05
5	100 (1.08) ⁵	146.93
17	100 (1.08) ¹⁷	370.00

To simplify, let's express the 8 percent annual interest rate as a decimal so that it becomes $i = 0.08$. The key to understanding compound interest is to realize that 1 year's worth of growth at interest rate i will always result in $(1 + i)$ times as much money at the end of a year as there was at the beginning of the year. Consequently, if the first year begins with \$100 and if $i = 0.08$, then $(1 + 0.08)$ or 1.08 times as much money—\$108—will be available at the end of the year. We show the computation for the first year in column 2 of Table 37.1 and display the \$108 outcome in column 3. The same logic would also apply with other initial amounts. If a year begins with \$500, there will be 1.08 times more money after 1 year, or \$540. Algebraically, let X_0 denote the amount of money at the start of the first year and X_1 the amount after 1 year's worth of growth. Then we see that any given number of dollars X_0 at the start of the first year grows into $X_1 = (1 + i)X_0$ dollars after one year's worth of growth.

Next, consider what happens if the initial investment of \$100 that grew into \$108 after 1 year continues to grow at 8 percent interest for a second year. The \$108 available at the beginning of the second year will grow into an amount of money that is 1.08 times larger by the end of the second year. That amount, as shown in Table 37.1, is \$116.64. Notice that the computation in the table is made by multiplying the initial \$100 by $(1.08)^2$. That is because the original \$100 is compounded by 1.08 into \$108 and then the \$108 is again compounded by 1.08. More generally, since the second year begins with $(1 + i)X_0$ dollars, it will grow to $(1 + i)(1 + i)X_0 = (1 + i)^2X_0$ dollars by the end of the second year.

Similar reasoning shows that the amount of money at the end of 3 years has to be $(1 + i)^3X_0$ since the amount of money at the beginning of the third year, $(1 + i)^2X_0$, gets multiplied by $(1 + i)$ to convert it into the amount of money at the end of the third year. In terms of Table 37.1, that amount is \$125.97, which is $(1.08)^3\$100$.

As you can see, we now have a fixed pattern. The \$100 that is invested at the beginning of the first year becomes $(1 + i)\$100$ after 1 year, $(1 + i)^2\$100$ after 2 years, $(1 + i)^3\$100$ after 3 years, and so on. It therefore is clear that the amount of money after t years will be $(1 + i)^t\$100$. This pattern always holds true, regardless of the size of the initial investment.

Thus, investors know that if X_0 dollars is invested today and earns compound interest at the rate i , it will grow into exactly $(1 + i)^tX_0$ dollars after t years. Economists express that fact with the following formula:

$$X_t = (1 + i)^tX_0 \quad (1)$$

Equation 1 captures the idea that if investors have the opportunity to invest X_0 dollars today at interest rate i , then they have the ability to transform X_0 dollars today into $(1 + i)^tX_0$ dollars in t years.

But notice that the logic of the equality also works in reverse, so that it can also be thought of as showing that $(1 + i)^tX_0$ dollars in t years can be transformed into X_0 dollars today. That may seem very odd, but it is exactly what happens when people take out loans. For instance, consider a situation where an investor named Roberto takes out a loan for \$100 dollars today, a loan that will accumulate interest at 8 percent per year for 5 years. Under such an arrangement, the amount Roberto owes will grow with compound interest into $(1.08)^5\$100 = \146.93 dollars in 5 years. This means that Roberto can convert \$146.93 dollars in 5 years (the amount required to pay off the loan) into \$100 dollars today (the amount he borrows).

Consequently, the compound interest formula given in equation 1 defines not only the rate at which present amounts of money can be converted to future amounts of money but also the rate at which future amounts of money can be converted into present amounts of money.

The Present Value Model

The present value model simply rearranges equation 1 to make it easier to transform future amounts of money into present amounts of money. To derive the formula used to calculate the present value of a future amount of money, we divide both sides of equation 1 by $(1 + i)^t$ to obtain

$$\frac{X_t}{(1 + i)^t} = X_0 \quad (2)$$

The logic of equation 2 is identical to that of equation 1. Both allow investors to convert present amounts of money into future amounts of money and vice versa. However, equation 2 makes it much more intuitive to convert a given number of dollars in the future into their present-day equivalent. In fact, it says that X_t dollars in t years converts into exactly $X_t/(1 + i)^t$ dollars today. This may not seem important, but it is actually very powerful because it allows investors to easily calculate how much they should pay for any given asset.

To see why this is true, understand that an asset's owner obtains the right to receive one or more future payments. If an investor is considering buying an asset, her problem is to try to determine how much she should pay today to buy the asset and receive those future payments. Equation 2 makes this task very easy. If she knows how large a future payment will

be (X_t dollars), when it will arrive (in t years), and what the interest rate (i) is, then she can apply equation 2 to determine the payment's present value: its value in present-day dollars. If she does this for each of the future payments that the asset in question is expected to make, she will be able to calculate the overall present value of all the asset's future payments by simply summing together the present values of each of the individual payments. This will allow her to determine the price she should pay for the asset. In particular, *the asset's price should exactly equal the sum of the present values of all of the asset's future payments.*

As a simple example, suppose that Cecilia has the chance to buy an asset that is guaranteed to return a single payment of exactly \$370.00 in 17 years. Again let's assume the interest rate is 8 percent per year. Then the present value of that future payment can be determined using equation 2 to equal precisely $\$370.00/(1 + 0.08)^{17} = \$370.00/(1.08)^{17} = \$100$ today. This is confirmed in the row for year 17 in Table 37.1.

To see why Cecilia should be willing to pay a price that is *exactly* equal to the \$100 present value of the asset's single future payment of \$370.00 in 17 years, consider the following thought experiment. What would happen if she were to invest \$100 today in an alternative investment that is guaranteed to compound her money for 17 years at 8 percent per year? How large would her investment in this alternative become? Equation 1 and Table 37.1 tell us that the answer is exactly \$370.00 in 17 years.

This is very important because it shows that Cecilia and other investors have two different possible ways of purchasing the right to receive \$370.00 in 17 years. They can either:

- Purchase the asset in question for \$100.
- Invest \$100 in the alternative asset that pays 8 percent per year.

Because either investment will deliver the same future benefit, both investments are in fact identical. Consequently, they should have identical prices—meaning that each will cost precisely \$100 today.

A good way to see why this must be the case is by considering how the presence of the alternative investment affects the behavior of both the potential buyers and the potential sellers of the asset in question. First, notice that Cecilia and other potential buyers would never pay more than \$100 for the asset in question because they know that they could get the same future return of \$370.00 in 17 years by investing \$100 in the alternative investment. At the same time, people selling the asset in question would not sell it to Cecilia or other potential buyers for anything less than \$100 since they know that the only other way for Cecilia and other potential buyers to get a future return of \$370.00 in 17 years is by paying \$100 for the alternative investment. Since Cecilia and the other potential buyers will not pay more than \$100 for the asset in question and its sellers will not accept less than \$100

for the asset in question, the result will be that the asset in question and the alternative investment will have the exact same price of \$100 today.

QUICK REVIEW 37.1

- ✓ Financial investment refers to buying an asset with the hope of financial gain.
- ✓ The time-value of money is the idea that a specific amount of money is more valuable to a person the sooner it is received because of the potential for compound interest.
- ✓ Compound interest is the payment of interest not only on the original amount invested but also on any interest payments previously made; X_0 dollars today growing at interest rate i will become $(1 + i)^t X_0$ dollars in t years.
- ✓ The present value formula facilitates transforming future amounts of money into present-day amounts of money; X_t dollars in t years converts into exactly $X_t/(1 + i)^t$ dollars today.
- ✓ An investment's proper current price is equal to the sum of the present values of all the future payments that it is expected to make.

Applications

Present value is not only an important idea for understanding investment, but it has many everyday applications. Let's examine two of them.

Take the Money and Run? The winners of state lotteries are typically paid their winnings in equal installments spread out over 20 years. For instance, suppose that Zoe gets lucky one week and wins a \$100 million jackpot. She will not be paid \$100 million all at once. Rather, she will receive \$5 million per year for 20 years, for a total of \$100 million.

Zoe may object to this installment payment system for a variety of reasons. For one thing, she may be very old, so that she is not likely to live long enough to collect all of the payments. Alternatively, she might prefer to receive her winnings immediately so that she could make large immediate donations to her favorite charities or large immediate investments in a business project that she would like to get started. And, of course, she may just be impatient and want to buy a lot of really expensive consumption goods sooner rather than later.

Fortunately for Zoe, if she does have a desire to receive her winnings sooner rather than later, several private financial companies are ready and willing to help her. They do this by arranging swaps. Lottery winners sell the right to receive their installment payments in exchange for a single lump sum that

they get immediately. The people who hand over the lump sum receive the right to collect the installment payments.

Present value is crucial to arranging these swaps since it is used to determine the value of the lump sum that lottery winners like Zoe will receive in exchange for giving up their installment payments. In any case, the lump sum is simply equal to the sum of the present values of each of the future payments. Assuming an interest rate of 5 percent per year, the sum of the present values of each of Zoe's 20 installment payments of \$5 million is \$62,311,051.71. So, depending on her preferences, Zoe can either receive that amount immediately or \$100 million spread out over 20 years.

Salary Caps and Deferred Compensation Another example of present value comes directly from the sporting news. Many professional sports leagues worry that richer teams, if not held in check, would outbid poorer teams for the best players. The result would be a situation in which only the richer teams have any real chance of doing well and winning championships.

To prevent this from happening, many leagues have instituted salary caps. These are upper limits on the total amount of money that each team can spend on salaries during a given season. For instance, one popular basketball league has a salary cap of about \$58 million per season, so that the combined value of the salaries that each team pays its players can be no more than \$58 million.

Typically, however, the salary contracts that are negotiated between individual players and their teams are for multiple seasons. This means that during negotiations, players are often asked to help their team stay under the current season's salary cap by agreeing to receive more compensation in later years. For instance, suppose that a team's current payroll is \$53 million but that it would like to sign a superstar nicknamed HiTop to a two-year contract. HiTop, however, is used to earning \$10 million per year. This is a major problem for the team because the \$58 million salary cap means that the most that the team can pay HiTop for the current season is \$5 million.

A common solution is for HiTop to agree to receive only \$5 million the first season in order to help the team stay under the salary cap. In exchange for this concession, the team agrees to pay HiTop more than the \$10 million he would normally demand for the second season. The present value formula is used to figure out how large his second-season salary should be. In particular, the player can use the present value formula to figure out that if the interest rate is 8 percent per year, he should be paid a total of \$15,400,000 during his second season, since this amount will equal the \$10 million he wants for the second season plus \$5.4 million to make up for the \$5 million reduction in his salary during the first season. That is, the present value of the \$5.4 million that he will receive during the second season precisely equals the \$5 million that he agrees to give up during the first season.

Some Popular Investments

L037.3 Identify and distinguish among the most common financial investments: stocks, bonds, and mutual funds.

The number and types of financial “instruments” in which one can invest are very numerous, amazingly creative, and highly varied. Most are much more complicated than the investments we used to explain compounding and present value. But, fortunately, all investments share three features:

- They require that investors pay some price—determined in the market—to acquire them.
- They give their owners the chance to receive future payments.
- The future payments are typically risky.

These features allow us to treat all assets in a unified way. Three of the more popular investments are stocks, bonds, and mutual funds. In 2013, the median value of stock holdings for U.S. families that held stocks was \$27,000; the median value for bonds, \$94,500; and the median value for “pooled funds” (mainly mutual funds) was \$80,000.¹

Stocks

Recall that **stocks** are ownership shares in a corporation. If an investor owns 1 percent of a corporation's shares, she gets 1 percent of the votes at the shareholder meetings that select the company's managers and she is also entitled to 1 percent of any future profit distributions. There is no guarantee, however, that a company will be profitable.

Firms often lose money and sometimes even go **bankrupt**, meaning that they are unable to make timely payments on their debts. In the event of a bankruptcy, control of a corporation's assets is given to a bankruptcy judge, whose job is to enforce the legal rights of the people who lent the company money by doing what he can to see that they are repaid. Typically, this involves selling off the corporation's assets (factories, real estate, patents, etc.) to raise the money necessary to pay off the company's debts. The money raised by selling the assets may be greater than or less than what is needed to fully pay off the firm's debts. If it is more than what is necessary, any remaining money is divided equally among shareholders. If it is less than what is necessary, then the lenders do not get repaid in full and have to suffer a loss.

A key point, however, is that the maximum amount of money that shareholders can lose is what they pay for their shares. If the company goes bankrupt owing more than the value of the firm's assets, shareholders do not have to make up the difference. This **limited liability rule** limits the risks involved in investing in corporations and encourages investors

¹Federal Reserve, “Changes in U.S. Family Finances from 2010–2013; Evidence from the Survey of Consumer Finances,” p. 16.

to invest in stocks by capping their potential losses at the amount that they paid for their shares.

When firms are profitable, however, investors can look forward to gaining financially in either or both of two possible ways. The first is through **capital gains**, meaning that they sell their shares in the corporation for more money than they paid for them. The second is by receiving **dividends**, which are equal shares of the corporation's profits. As we will soon explain, a corporation's current share price is determined by the size of the capital gains and dividends that investors expect the corporation to generate in the future.

Bonds

Bonds are debt contracts that are issued most frequently by governments and corporations. They typically work as follows: An initial investor lends the government or the corporation a certain amount of money, say \$1,000, for a certain period of time, say 10 years. In exchange, the government or corporation promises to make a series of semiannual payments in addition to returning the \$1,000 at the end of the 10 years. The semiannual payments constitute interest on the loan. For instance, the bond agreement may specify that the borrower will pay \$30 every six months. This means that the bond will pay \$60 per year in payments, which is equivalent to a 6 percent rate of interest on the initial \$1,000 loan.

The initial investor is free, however, to sell the bond at any time to other investors, who then gain the right to receive any of the remaining semiannual payments as well as the final \$1,000 payment when the bond expires after 10 years. As we will soon demonstrate, the price at which the bond will sell if it is indeed sold to another investor will depend on the current rates of return available on other investments offering a similar stream of future payments and facing a similar level of risk.

The primary risk a bondholder faces is the possibility that the corporation or government that issues his bond will **default** on, or fail to make, the bond's promised payments. This risk is much greater for corporations, but it also faces local and state governments in situations where they cannot raise enough tax revenue to make their bond payments or where defaulting on bond payments is politically easier than reducing spending on other items in the government's budget to raise the money needed to keep making bond payments. The U.S. federal government, however, has never defaulted on its bond payments and is very unlikely to ever default because it has access to huge amounts of current and potential tax revenue and can sell U.S. securities to the Fed as a way to obtain money.

A key difference between bonds and stocks is that bonds are much more predictable. Unless a bond goes into default, its owner knows both how big its future payments will be and exactly when they will arrive. By contrast, stock prices and dividends are highly volatile because they depend on profits,

which vary greatly depending on the overall business cycle and on factors specific to individual firms and industries—things such as changing consumer preferences, variations in the costs of inputs, and changes in the tax code. As we will demonstrate later, the fact that bonds are typically more predictable (and thus less risky) than stocks explains why they generate lower average rates of return than stocks. Indeed, this difference in rates of return has been very large historically. From 1926 to 2015, stocks on average returned about 11 percent per year worldwide, while bonds on average returned only roughly 6 percent per year worldwide.

Mutual Funds

A **mutual fund** is a company that maintains a professionally managed **portfolio**, or collection, of either stocks or bonds. The portfolio is purchased by pooling the money of many investors. Since these investors provide the money to purchase the portfolio, they own it and any gains or losses generated by the portfolio flow directly to them. Table 37.2 lists the 10 largest U.S. mutual funds based on their assets.

Most of the more than 8,000 mutual funds currently operating in the United States choose to maintain portfolios that invest in specific categories of bonds or stocks. For instance, some fill their portfolios exclusively with the stocks of small tech companies, while others buy only bonds issued by certain state or local governments. In addition, there are **index funds**, whose portfolios are selected to exactly match a stock or bond index. Indexes follow the performance of a particular group of stocks or bonds to gauge how well a particular category of investments is doing. For instance, the Standard & Poor's 500 Index contains the 500 largest stocks trading in the United States to capture how the stocks of large corporations vary over time.

*The letter A indicates funds that have sales commissions and are generally purchased by individuals through their financial advisors.

An important distinction must be drawn between actively managed and passively managed mutual funds. **Actively managed funds** have portfolio managers who constantly buy and sell assets in an attempt to generate high returns. By contrast, index funds are **passively managed funds** because the assets in their portfolios are chosen to exactly match whatever stocks or bonds are contained in their respective underlying indexes.

Later in the chapter, we will discuss the relative merits of actively managed funds and index funds, but for now we merely point out that both types are very popular and that, overall, U.S. households and nonprofit organizations held \$8.1 trillion in mutual funds at the end of 2015. By way of comparison, U.S. GDP in 2015 was \$17.9 trillion and the estimated value of all the financial assets held by households and nonprofit organizations in 2015 (including everything from individual stocks and bonds to checking account deposits) was about \$70 trillion.

Calculating Investment Returns

LO37.4 Relate how percentage rates of return provide a common framework for comparing assets and explain why asset prices and rates of return are inversely related.

Investors buy assets to obtain one or more future payments. The simplest case is purchasing an asset for resale. For instance, an investor may buy a house for \$300,000 with the hope of selling it for \$360,000 in one year. On the other hand, he could also rent out the house for \$3,000 per month and thereby receive a stream of future payments. And he, of course, could do a little of both, paying \$300,000 for the house now to rent it out for five years and then sell it. In that case, he is expecting a stream of smaller payments followed by a large one.

Percentage Rates of Return

Economists have developed a common framework for evaluating the gains or losses of assets that only make one future payment as well as those that make many future payments.

They state the gain or loss as a **percentage rate of return**, by which they mean the percentage gain or loss (relative to the buying price) over a given period of time, typically a year. For instance, if Noelle buys a rare comic book today for \$100 and sells it in 1 year for \$125, she is said to make a 25 percent per year rate of return because she would divide the gain of \$25 by the purchase price of \$100. By contrast, if she were only able to sell it for \$92, then she would be said to have made a loss of 8 percent per year since she would divide the \$8 loss by the purchase price of \$100.

A similar calculation is made for assets that deliver a series of payments. For instance, an investor who buys a house for \$300,000 and expects to rent it out for \$3,000 per month would be expecting to make a 12 percent per year rate of return because he would divide his \$36,000 per year of rent by the \$300,000 purchase price of the house.

Corporate Ownership

The rise of mutual funds has radically changed the way corporations are controlled. Before the 1970s, corporations knew that the vast majority of their shares were owned by individuals, the large majority of whom were interested in holding their shares for the long run. Those long-run individual investors paid close attention to what corporate officers were doing and would reprimand bad decisions at annual shareholder meetings.

By contrast, neither actively nor passively managed funds have much incentive to care about the long-run success of the companies whose shares they buy and sell.

Consider actively managed funds. Their managers lack an incentive to care about long-term performance because they are paid bonuses that depend almost entirely on quarterly performance rather than long-term performance. At the same time, the managers of passively managed funds have no incentive to care about corporate management or policy initiatives because they simply buy whatever stocks are included in their funds' respective underlying indexes.

Critics worry that the decline of close scrutiny by individual shareholders has helped to exacerbate a variety of problems, including corporate managers being paid excessive salaries and CEOs being overly focused on accounting gimmicks that offer a short-run boost to company share prices rather than good management decisions that will pay off only after many years have passed.

The Inverse Relationship between Asset Prices and Rates of Return

A fundamental concept in financial economics is that, other things equal, *an investment's rate of return is inversely related to its price*. The higher the price paid for a fixed-return asset, the lower the rate of return on the investment. To see why, consider a bond that pays \$24,000 of interest each year. If an investor pays \$100,000 for the bond, he will earn a 24 percent per year rate of return because the \$24,000 annual interest payment will be divided by the \$100,000 purchase price of the bond.

But suppose that the purchase price of the bond rises to \$200,000. In that case, the investor would earn only a 12 percent per year rate of return, since the \$24,000 annual interest payment would be divided by the much larger purchase price of \$200,000. Consequently, as the price of the bond goes up, the rate of return from buying it goes down.

The same relationship holds for other fixed-return investments, such as rental property. The higher the price of the property, given its monthly rent, the lower the rate of return. The underlying cause of this general relationship is the fact that the annual payments are fixed in value so that there is an upper limit to the financial rewards of owning the asset. As a result, the more an investor pays for the asset, the lower the asset's rate of return.

Arbitrage

L037.5 Define and utilize the concept of arbitrage.

Arbitrage is the name that financial economists give to the buying and selling process that leads profit-seeking investors to equalize the average expected rates of return generated by identical or nearly identical assets. Arbitrage happens when investors try to take advantage and profit from situations where two identical or nearly identical assets have different rates of return. They do so by simultaneously selling the asset with the lower rate of return and buying the asset with the higher rate of return. For instance, consider what would happen in a case where two very similar T-shirt companies start with different rates of return despite the fact that they are equally profitable and have equally good future prospects. To make things concrete, suppose that a company called T4me starts out with a rate of return of 10 percent per year while TSTG (T-Shirts to Go) starts out with a rate of return of 15 percent per year.

Since both companies are basically identical and have equally good prospects, investors in T4me will want to shift over to TSTG, which offers higher rates of return for the same amount of risk. As they begin to shift over, however, the prices of the two companies will change—and with them, the rates of return on the two companies. In particular, since so many investors will be selling the shares of the lower-return company, T4me, the supply of its shares trading on the stock

market will rise so that its share price will fall. But since asset prices and rates of return are inversely related, this will cause its rate of return to rise.

At the same time, however, the rate of return on the higher-return company, TSTG, will begin to fall. This has to be the case because, as investors switch from T4me to TSTG, the increased demand for TSTG's shares will drive up their price. And as the price of TSTG goes up, its rate of return must fall.

The interesting thing is that this arbitrage process will continue—with the rate of return on the higher-return company falling and the rate of return on the lower-return company rising—until both companies have the same rate of return. This convergence must happen because as long as the rates of return on the two companies are not identical, there will always be some investors who will want to sell the shares of the lower-return company so they can buy the shares of the higher-return company. As a result, arbitrage will continue until the rates of return are equal.

What is even more impressive, however, is that generally only a very short while is needed for prices to equalize. In fact, for highly traded assets like stocks and bonds, arbitrage will often force the rates of return on identical or nearly identical investments to converge within a matter of minutes or sometimes even within a matter of seconds. This is very helpful to small investors who do not have a large amount of time to study the thousands of potential investment opportunities available in the financial markets. Thanks to arbitrage, they can invest with the confidence that assets with similar characteristics will have similar rates of return. As we discuss in the next section, this is especially important when it comes to risk—a characteristic that financial economists believe investors care about very deeply.

QUICK REVIEW 37.3

- ✓ Stating gains or losses as percentage rates of return provides a common framework for comparing different assets.
- ✓ Asset prices and percentage rates of return are inversely related.
- ✓ Arbitrage refers to the buying and selling that takes place to equalize the percentage rates of return on identical or nearly identical assets.

Risk

L037.6 Describe how the word *risk* is used in financial economics and explain the difference between diversifiable and nondiversifiable risk.

Investors purchase assets to obtain one or more future payments. As used by financial economists, the word **risk** refers to the fact that investors never know with total certainty what those future payments will turn out to be.

The underlying problem is that the future is uncertain. Many factors affect an investment's future payments, and each of these may turn out better or worse than expected. As a simple example, consider buying a farm. Suppose that in an average year, the farm will generate a profit of \$100,000. But if a freak hailstorm damages the crops, the profit will fall to only \$60,000. On the other hand, if weather conditions turn out to be perfect, the profit will rise to \$120,000. Since there is no way to tell in advance what will happen, investing in the farm is risky.

Also notice that when financial economists use the word *risk*, they do not use it in the casual way that refers only to potentially bad outcomes (as in, “there is a risk that this experimental medicine may kill you”). In financial economics, the word *risk* means only that an outcome—good or bad, major or minor, likely or unlikely—lacks total certainty. Some outcome will occur, but you cannot be sure what it will be. For instance, suppose that you are gifted a raffle ticket that will pay you \$10, \$100, or \$1,000 when a drawing is made in one month. There are no bad outcomes in this particular case, only good ones. But because you do not know with certainty which outcome will occur, the situation is, by definition, risky. On the other hand, the word *risk* in financial economics certainly does not preclude negative outcomes. If you buy shares of common stock in some company, your stock may go up in value. But the company could also go bankrupt, in which case you would lose your entire investment.

Diversification

Investors have many options regarding their portfolios, or collections of investments. Among other things, they can choose to concentrate their wealth in just one or two investments or spread it out over a large number of investments. **Diversification** is the name given to the strategy of investing in a large number of investments to reduce the overall risk to the entire portfolio.

The underlying reason that diversification generally succeeds in reducing risk is best summarized by the old saying, “Don’t put all your eggs in one basket.” If an investor’s portfolio consists of only one investment—say, one stock—then if anything awful happens to that stock, the investor’s entire portfolio will suffer greatly. By contrast, if the investor spreads his wealth over many stocks, then a bad outcome for any one particular stock will cause only a small amount of damage to the overall portfolio. In addition, it will typically be the case that if something bad is happening to one part of the portfolio, something good will be happening to another part of the portfolio and the two effects will tend to offset each other. Thus, the risk to the overall portfolio is reduced by diversification.

It must be stressed, however, that while diversification can reduce a portfolio’s risks, it cannot eliminate them entirely. The problem is that even if an investor has placed each

of his eggs into a different basket, all of the eggs may still end up broken if all of the different baskets somehow happen to get dropped simultaneously. That is, even if an investor has created a well-diversified portfolio, all of the investments still have a chance to do badly simultaneously. As an example, consider the early portion of the severe recession of 2007–2009: With economic activity declining and consumer spending falling, nearly all companies faced reduced sales and lowered profits, a fact that caused their stock prices to decline simultaneously. Consequently, even if investors had diversified their portfolios across numerous stocks, their overall wealth portfolios would have still declined because nearly all of their many investments simultaneously performed poorly.

Financial economists build on the intuition behind the benefits and limits to diversification to divide an individual investment’s overall risk into two components, diversifiable risk and nondiversifiable risk. **Diversifiable risk** (or “idiosyncratic risk”) is the risk that is specific to a given investment and that can be eliminated by diversification. For instance, a soda pop maker faces the risk that the demand for its product may suddenly decline because people will want to drink mineral water instead of soda pop. But this risk does not matter if an investor has a diversified portfolio that contains stock in the soda pop maker as well as stock in a mineral water maker. This is true because when the stock price of the soda pop maker falls due to the change in consumer preferences, the stock price of the mineral water maker will go up—so that, as far as the overall portfolio is concerned, the two effects will offset each other.

By contrast, **nondiversifiable risk** (or “systemic risk”) pushes all investments in the same direction at the same time so that there is no possibility of using good effects to offset bad effects. The best example of a nondiversifiable risk is the business cycle. If the economy does well, then corporate profits rise and nearly every stock does well. But if the economy does badly, then corporate profits fall and nearly every stock does badly. As a result, even if one were to build a well-diversified portfolio, it would still be affected by the business cycle because nearly every asset contained in the portfolio would move in the same direction at the same time whenever the economy improved or worsened.

That being said, creating a diversified portfolio is still an investor’s best strategy because doing so at least eliminates diversifiable risk. Indeed, it should be emphasized that for investors who have created diversified portfolios, all diversifiable risks will be eliminated, so that the only remaining source of risk will be nondiversifiable risk.

A significant implication of this fact is that when investors consider whether to add any particular investment to a portfolio that is already diversified, they can ignore the investment’s diversifiable risk. They can ignore it because, as part of a diversified portfolio, the investment’s diversifiable risk will be “diversified away.” Indeed, the only risk left will be the

Investment Risks Vary across Different Countries

The *International Country Risk Guide* is a monthly publication that attempts to distill the political, economic, and financial risks facing 140 countries into a single “composite risk rating” number for each country, with higher numbers indicating less risk and more safety. The table below presents the January 2016 ranks and rating numbers for 15 countries including the three least risky (ranked 1 through 3) and the three most risky (ranked 138 through 140). Risk ratings numbers above 80 are considered *very low risk*; 70–80 are considered *low risk*; 60–70 *moderate risk*; 50–60 *high risk*; and below 50 *very high risk*.

amount of nondiversifiable risk that the investment carries with it. This is crucial because it means that investors can base their decisions about whether to add a potential new investment to their portfolios on a comparison between the potential investment’s level of nondiversifiable risk and its potential returns. If they find this trade-off attractive, they will add the investment, whereas if it seems unattractive, they will not.

The next section shows how investors can measure each asset’s level of nondiversifiable risk as well as its potential returns to facilitate such comparisons. Global Perspective 37.1 shows how investment risk varies significantly across countries due to underlying differences in political, economic, and financial risks.

QUICK REVIEW 37.4

- ✓ An asset is risky if its future payments are uncertain.
- ✓ Diversification is an investment strategy in which an investor invests in a large number of different investments in order to reduce the overall risk to his or her entire portfolio.
- ✓ Risks that can be canceled out by diversification are called diversifiable risks; risks that cannot be canceled out by diversification are called nondiversifiable risks.

Comparing Risky Investments

L037.7 Convey why investment decisions are determined primarily by investment returns and nondiversifiable risk and how investment returns compensate for being patient and for bearing nondiversifiable risk.

Economists believe that the two most important factors affecting investment decisions are returns and risk—specifically nondiversifiable risk. But for investors to properly compare different investments on the basis of returns and risk, they need ways to measure returns and risk. The two standard measures are, respectively, the average expected rate of return and the beta statistic.

Average Expected Rate of Return

Each investment’s **average expected rate of return** is the probability-weighted average of the investment’s possible future rates of return. The term **probability-weighted average** simply means that each of the possible future rates of return is multiplied by its probability expressed as a decimal (so that a 50 percent probability is 0.5 and a 23 percent probability is 0.23) before being added together to obtain the average. For instance, if an investment has a 75 percent probability of generating 11 percent per year and a 25 percent probability of generating 15 percent per year, then its average expected rate of return will be 12 percent = $(0.75 \times 11 \text{ percent}) + (0.25 \times 15 \text{ percent})$. By weighting each possible outcome by its probability, this process ensures that the resulting average gives more weight to those outcomes that are more likely to happen (unlike the normal averaging process that would treat every outcome the same).

Once investors have calculated the average expected rates of return for all the assets they are interested in, there will naturally be some impulse to simply invest in those assets having the highest average expected rates of return. But while this might satisfy investor cravings for higher rates of return, it would not take proper account of the fact that investors dislike risk and uncertainty. To quantify their dislike, investors require a statistic that can measure each investment’s risk level.

Beta

One popular statistic that measures risk is called beta. **Beta** is a *relative* measure of nondiversifiable risk. It measures how the nondiversifiable risk of a given asset or portfolio of assets compares with that of the **market portfolio**, which is the name given to a portfolio that contains every asset available in the financial markets. The market portfolio is a useful standard of comparison because it is as diversified as possible. In fact, since it contains every possible asset, every possible diversifiable risk will be diversified away—meaning that it will be exposed *only* to nondiversifiable risk. Consequently, it can serve as a useful benchmark against which to measure the levels of nondiversifiable risk to which individual assets are exposed.

Such comparisons are very simple because the beta statistic is standardized such that the market portfolio's level of nondiversifiable risk is set equal to 1.0. Consequently, an asset with $\beta = 0.5$ has a level of nondiversifiable risk that is one-half of that possessed by the market portfolio, while an asset with $\beta = 2.0$ has twice as much nondiversifiable risk as the market portfolio. In addition, the beta numbers of various assets also can be used to compare them with each other. For instance, an asset with $\beta = 2.0$ has four times as much exposure to nondiversifiable risk as does an asset with $\beta = 0.5$.

Another useful feature of beta is that it can be calculated not only for individual assets but also for portfolios. Indeed, it can be calculated for portfolios no matter how many or how few assets they contain and no matter what those assets happen to be. This fact is very convenient for mutual fund investors because it means that they can use beta to quickly see how the nondiversifiable risk of any given fund's portfolio compares with that of other potential investments that they may be considering.

The beta statistic is used along with average expected rates of return to give investors standard measures of risk and return that can be used to sensibly compare different investment opportunities. As we will discuss in the next section, this leads to one of the most fundamental relationships in financial economics: riskier assets have higher rates of return.

Relationship of Risk and Average Expected Rates of Return

The fact that investors dislike risk has a profound effect on asset prices and average expected rates of return. In particular, their dislike of risk and uncertainty causes investors to pay higher prices for less-risky assets and lower prices for more-risky assets. But since asset prices and average expected rates of return are inversely related, this implies that less-risky assets will have lower average expected rates of return than more-risky assets.

Stated a bit more clearly: *Risk levels and average expected rates of return are positively related.* The more risky an

investment is, the higher its average expected rate of return will be. A great way to understand this relationship is to think of higher average expected rates of return as being a form of compensation. Since investors dislike risk, they demand higher levels of compensation the more risky an asset is. The higher levels of compensation come in the form of higher average expected rates of return.

Be sure to note that this phenomenon affects all assets. Regardless of whether the assets are stocks or bonds or real estate or anything else, assets with higher levels of risk always end up with higher average expected rates of return to compensate investors for the higher levels of risk involved. No matter what the investment opportunity is, investors examine its possible future payments, determine how risky they are, and then select a price that reflects those risks. Since less-risky investments get higher prices, they end up with lower rates of return, whereas more-risky investments end up with lower prices and, consequently, higher rates of return.

The Risk-Free Rate of Return

We have just shown that there is a positive relationship between risk and returns, with higher returns serving to compensate investors for higher levels of risk. One investment, however, is considered to be risk-free for all intents and purposes. That investment is short-term U.S. government bonds.

These bonds are short-term loans to the U.S. government, with the duration of the loans ranging from 4 weeks to 26 weeks. They are considered to be essentially risk-free because there is almost no chance that the U.S. government will not be able to repay these loans on time and in full. To pay its debt, it can shift funds within its enormous budget, raise taxes, or borrow newly created money from the Fed. Although it is true that the U.S. government may eventually be destroyed or disabled to such an extent that it will not be able to repay some of its loans, the chances of such a calamity happening within 4 or even 26 weeks are essentially zero. Consequently, because it is a near certainty that the bonds will be repaid in full and on time, they are considered by investors to be risk-free.

Since higher levels of risk lead to higher rates of return, a person might be tempted to assume—incorrectly—that since government bonds are risk-free, they should earn a zero percent rate of return. The problem with this line of thinking is that it mistakenly assumes that risk is the *only* thing that rates of return compensate for. The truth is that rates of return compensate not only for risk but also for something that economists call time preference.

Time preference refers to the fact that because people tend to be impatient, they typically prefer to consume things in the present rather than in the future. Stated more concretely,

most people, if given the choice between a serving of their favorite dessert immediately or a serving of their favorite dessert in five years, will choose to consume their favorite dessert immediately.

This time preference for consuming sooner rather than later affects the financial markets because people want to be compensated for delayed consumption. In particular, if Dave asks Oprah to lend him \$1 million for one year, he is implicitly asking Oprah to delay consumption for a year because if she lends Dave the \$1 million, she will not be able to spend that money herself for at least a year. If Oprah is like most people and has a preference for spending her \$1 million sooner rather than later, the only way Dave will be able to convince Oprah to let him borrow \$1 million is to offer her some form of compensation. The compensation comes in the form of an interest payment that will allow Oprah to consume more in the future than she can now. For instance, Dave can offer to pay Oprah \$1.1 million in one year in exchange for \$1 million today. That is, Oprah will get back the \$1 million she lends to Dave today as well as an extra \$100,000 to compensate her for being patient.

Notice the very important fact that this type of interest payment has nothing to do with risk. It is purely compensation for being patient and must be paid even if there is no risk involved and 100 percent certainty that Dave will fulfill his promise to repay.

Since short-term U.S. government bonds are for all intents and purposes completely risk-free and 100 percent likely to repay as promised, their rates of return are *purely* compensation for time preference and the fact that people must be compensated for delaying their own consumption opportunities when they lend money to the government. One consequence of this fact is that the rate of return earned by short-term U.S. government bonds is often referred to as the **risk-free interest rate**, or i^f , to clearly indicate that the rate of return that they generate is not in any way a compensation for risk.

It should be kept in mind, however, that the Federal Reserve has the power to change the risk-free interest rate generated by short-term U.S. government bonds. As discussed in Chapter 36, the Federal Reserve can use open-market operations to lower or raise the federal funds interest rate by making large purchases or sales of U.S. securities in the bond market. These open-market operations affect the money supply, which affects all interest rates, including the rates on short-term U.S. government bonds. This means that the Federal Reserve indirectly determines the risk-free interest rate and, consequently, the compensation that investors receive for being patient. As we will soon demonstrate, this fact is very important because by manipulating the reward for being patient, the Federal Reserve can affect the rate of return and prices of not only government bonds but all assets.

QUICK REVIEW 37.5

- ✓ The average expected rate of return is the probability-weighted average of an investment's possible future returns.
- ✓ Beta measures the nondiversifiable risk of an investment relative to the amount of nondiversifiable risk facing the market portfolio, which is the portfolio containing every asset available in the financial markets.
- ✓ Because investors dislike risk, riskier investments must offer higher rates of return to compensate investors for bearing more risk.
- ✓ Average expected rates of return compensate investors for both risk and time preference, which is the preference most people have to consume sooner rather than later.

The Security Market Line

L037.8 Explain how the Security Market Line illustrates the compensation that investors receive for time preference and nondiversifiable risk and why arbitrage will tend to move all assets onto the Security Market Line.

Investors must be compensated for time preference as well as for the amount of nondiversifiable risk that an investment carries with it. This section introduces a simple model called the **Security Market Line**, which indicates how this compensation is determined for all assets no matter what their respective risk levels happen to be.

The underlying logic of the model is this: Any investment's average expected rate of return has to be the sum of two parts—one that compensates for time preference and another that compensates for risk. That is,

$$\begin{aligned} \text{Average expected} &= \text{rate that compensates for} \\ \text{rate of return} & \quad \text{time preference} \\ & \quad + \text{rate that compensates for risk} \end{aligned}$$

As we explained, the compensation for time preference is equal to the risk-free interest rate, i^f , that is paid on short-term government bonds. As a result, this equation can be simplified to

$$\begin{aligned} \text{Average expected} &= i^f + \text{rate that compensates} \\ \text{rate of return} & \quad \text{for risk} \end{aligned}$$

Finally, because economists typically refer to the rate that compensates for risk as the **risk premium**, this equation can be simplified even further to

$$\text{Average expected rate of return} = i^f + \text{risk premium}$$

Naturally, the size of the risk premium that compensates for risk will vary depending on how risky an investment happens to be. In particular, it will depend on how big or small the investment's beta is. Investments with large

FIGURE 37.1 The Security Market Line. The Security Market Line shows the relationship between average expected rates of return and risk levels that must hold for every asset or portfolio trading in the financial markets. Each investment's average expected rate of return is the sum of the risk-free interest rate that compensates for time preference as well as a risk premium that compensates for the investment's level of risk. The Security Market Line's upward slope reflects the fact that investors must be compensated for higher levels of risk with higher average expected rates of return.

betas and lots of nondiversifiable risk will require larger risk premiums than investments that have small betas and low levels of nondiversifiable risk. And, in the most extreme case, risk-free assets that have betas equal to zero will require no compensation for risk at all since they have no risk to compensate for.

This logic is translated into the graph presented in Figure 37.1. The horizontal axis of Figure 37.1 measures risk levels using beta; the vertical axis measures average expected rates of return. As a result, any investment can be plotted on Figure 37.1 just as long as we know its beta and its average expected rate of return. We have plotted two investments in Figure 37.1. The first is a risk-free short-term U.S. government bond, which is indicated by the lower-left dot in the figure. The second is the market portfolio, which is indicated by the upper-right dot in the figure.

The lower dot marking the position of the risk-free bond is located where it is because it is a risk-free asset having a $\beta = 0$ and because its average expected rate of return is given by i^f . These values place the lower dot i^f percentage points up the vertical axis, as shown in Figure 37.1. Note that this location conveys the logic that because this asset has no risk, its average expected rate of return only has to compensate investors for time preference—which is why its average expected rate of return is equal to precisely i^f and no more.

The market portfolio, by contrast, is risky so that its average expected rate of return must compensate investors not

only for time preference but also for the level of risk to which the market portfolio is exposed, which by definition is $\beta = 1.0$. This implies that the vertical distance from the horizontal axis to the upper dot is equal to the sum of i^f and the market portfolio's risk premium.

The straight line connecting the risk-free asset's lower dot and the market portfolio's upper dot is called the Security Market Line, or SML. The SML is extremely important because it defines the relationship between average expected rates of return and risk levels that must hold for all assets and all portfolios trading in the financial markets. The SML illustrates the idea that every asset's average expected rate of return is the sum of a rate of return that compensates for time preference and a rate of return that compensates for risk. More specifically, the SML has a vertical intercept equal to the rate of interest earned by short-term U.S. government bonds and a positive slope that compensates investors for risk.

As we explained earlier, the precise location of the intercept at any given time is determined by the Federal Reserve's monetary policy and how it affects the rate of return on short-term U.S. government bonds. The slope of the SML, however, is determined by investors' feelings about risk and how much compensation they require for dealing with it. If investors greatly dislike risk, then the SML will have to be very steep, so that any given increase in risk on the horizontal axis will result in a very large increase in compensation as measured by average expected rates of return on the vertical axis. On the other hand, if investors dislike risk only moderately, then the SML will be relatively flat since any given increase in risk on the horizontal axis would require only a moderate increase in compensation as measured by average expected rates of return on the vertical axis.

It is important to realize that once investor preferences about risk have determined the slope of the SML and monetary policy has determined its vertical intercept, the SML plots out the precise relationship between risk levels and average expected rates of return *that should hold for every asset*. For instance, consider Figure 37.2, where there is an asset whose risk level on the horizontal axis is $\beta = X$. The SML tells us that every asset with that risk level should have an average expected rate of return equal to Y on the vertical axis. This average expected rate of return exactly compensates for both time preference and the fact that the asset in question is exposed to a risk level of $\beta = X$.

Finally, it should be pointed out that arbitrage will ensure that all investments having an identical level of risk also will have an identical rate of return—the return given by the SML. This is illustrated in Figure 37.3, where the three assets A, B, and C all share the same risk level of $\beta = X$ but initially have three different average expected rates of return. Since asset B lies on the SML, it has the average expected rate of return Y that precisely compensates investors for time preference and risk level X . Asset A, however, has a higher average expected rate of return that overcompensates investors while

FIGURE 37.2 Risk levels determine average expected rates of return. The Security Market Line can be used to determine an investment's average expected rate of return based on its risk level. In this figure, investments having a risk level of $\beta = X$ will have an average expected rate of return of Y percent per year. This average expected rate of return will compensate investors for time preference in addition to providing them exactly the right-sized risk premium to compensate them for dealing with a risk level of $\beta = X$.

asset C has a lower average expected rate of return that undercompensates investors.

Arbitrage pressures will quickly eliminate these over- and undercompensations. For instance, consider what will happen to asset A. Investors will be hugely attracted to its overly high rate of return and will rush to buy it. That will drive up its price. But because average expected rates of return and prices are inversely related, the increase in price will cause its average expected rate of return to fall. Graphically, this means that asset A will move vertically downward as illustrated in Figure 37.3. And it will continue to move vertically downward until it reaches the SML since only then will it have the average expected rate of return Y that properly compensates investors for time preference and risk level X .

A similar process also will move asset C back to the SML. Investors will dislike the fact that its average expected rate of return is so low. This will cause them to sell it, driving down its price. Since average expected rates of return and prices are inversely related, this will cause its average expected rate of return to rise, thereby causing C to rise vertically as illustrated in Figure 37.3. And as with point A, point C will continue to rise until it reaches the SML, since only then will it have the average expected rate of return Y that properly compensates investors for time preference and risk level X .

Security Market Line: Applications

The SML analysis is highly useful in clarifying why investors scrutinize the intentions and actions of the Federal Reserve and change their behaviors during financial crises.

FIGURE 37.3 Arbitrage and the Security Market Line. Arbitrage pressures will tend to move any asset or portfolio that lies off the Security Market Line back onto the line. Investors will increase their purchases of asset A, driving up its price and decreasing its average expected rate of return. They will decrease their purchases of asset C, reducing its price and raising its return. Therefore, assets A, B, and C will all end up on the Security Market Line with each having the same average expected rate of return, Y , at risk level (beta) X . This average expected rate of return will fully compensate the investors for time preference plus nondiversifiable risk as measured by beta.

An Increase in the Risk-Free Rate by the Fed We have just explained how the position of the Security Market Line is fixed by two factors. The vertical intercept is set by the risk-free interest rate while the slope is determined by the amount of compensation investors demand for bearing nondiversifiable risk. As a result, changes in either one of these factors can shift the SML and thereby cause large changes in both average expected rates of return and asset prices.

As an example, consider what happens to the SML if the Federal Reserve changes policy and uses open-market operations (described in Chapter 36) to reduce the money supply, raise the federal funds rate, and increase other interest rates such as those on short-term U.S. government bonds. Since the risk-free interest rate earned by these bonds is also the SML's vertical intercept, an increase in their interest rate will move the SML's vertical intercept upward, as illustrated in Figure 37.4. The result is a parallel upward shift of the SML from SML_1 to SML_2 . (The shift is parallel because nothing has happened that would affect the SML's slope, which is determined by the amount of compensation that investors demand for bearing risk.)

Notice what this upward shift implies. Not only does the rate of return on short-term U.S. government bonds increase when the Federal Reserve changes policy, but the rate of return on risky assets increases as well. For instance, consider asset A, which originally has rate of return Y_1 . After the SML shifts upward, asset A ends up with the higher rate of return Y_2 . There is a simple intuition behind this increase. Risky assets must

FIGURE 37.4 An increase in risk-free interest rates causes the SML to shift up vertically. The risk-free interest rate set by the Federal Reserve is the Security Market Line's vertical intercept. Consequently, if the Federal Reserve increases the risk-free interest rate, the Security Market Line's vertical intercept will move up. This rise in the risk-free interest rate will result in a decline in all asset prices and thus an increase in the average expected rate of return on all assets. So the Security Market Line will shift up parallel from SML_1 to SML_2 . Here, asset A with risk level $\beta = X$ sees its average expected rate of return rise from Y_1 to Y_2 .

compete with risk-free assets for investor money. When the Federal Reserve increases the rate of return on risk-free short-term U.S. government bonds, they become more attractive to investors. But to get the money to buy more risk-free bonds, investors have to sell risky assets. This drives down their prices and—because prices and average expected rates of return are inversely related—causes their average expected rates of return to increase. The result is that asset A moves up vertically in Figure 37.4, its average expected rate of return increasing from Y_1 to Y_2 as investors reallocate their wealth from risky assets like asset A to risk-free bonds.

This process explains why investors are so watchful of the Federal Reserve and keenly interested in its policies. Any increase in the risk-free interest rate leads to a decrease in asset prices that directly reduces investors' wealth.

The Fed's power to change asset prices through monetary policy stems entirely from the fact that changes in the risk-free rate shift the SML and thus totally redefine the investment opportunities available in the economy. As the set of options changes, investors modify their portfolios to obtain the best possible combination of risk and returns from the new set of investment options. In doing so, they engage in massive amounts of buying and selling to get rid of assets they no longer want and acquire assets that they now desire. These massive changes in supply and demand for financial assets are what cause their prices to change so drastically when the Federal Reserve alters the risk-free interest rate.

The Security Market Line during the Great Recession

The special circumstances of the financial markets during the recession of 2007–2009 provide an excellent illustration of both the impact of Federal Reserve actions and the idea of *time-varying risk premium*. The latter is the reality that the premium demanded by investors to take on risk may vary from one period (and one set of economic circumstances) to another period (and a different set of economic circumstances).

The Federal Reserve used expansionary monetary policy during this period to lower interest rates, including the interest rates of short-term U.S. government bonds. Because the risk-free interest rate earned by these securities locates the vertical intercept of the Securities Market Line, the actual SML for the economy shifted downward from that shown in Figure 37.1. This decline would be portrayed as the opposite of the upward shift that we illustrate in Figure 37.4.

But wouldn't we expect stock market prices to rise when the risk-free rate of return falls? That certainly did *not* happen in 2007 and 2008. Yes, normally, stock market prices rise when the risk-free interest rate falls. But during this unusual period, investors became very fearful about losses from investments in general and began to look for any place of financial safety. As their appetite for risk decreased, they demanded a much higher rate of compensation for taking on any particular level of risk. In terms of Figure 37.4, the slope of the SML greatly increased. Thus, between the Fed's deliberate reduction of the risk-free rate and investors' diminished appetite for risk, two things happened at once to the SML: (1) Its intercept (the risk-free rate) dramatically fell and (2) the SML became much steeper. In Figure 37.1, these two effects would be shown by a much steeper SML emanating from a much lower point on the vertical axis.

The increase in the slope of the SML overwhelmed the decline in the intercept. Investors sold off stocks, which greatly reduced stock prices, even though the risk-free interest rate fell.

QUICK REVIEW 37.6

- ✓ The Security Market Line (SML) is a straight, upsloping line showing how the average expected rates of return on investments vary with their respective levels of nondiversifiable risk as measured by beta.
- ✓ Arbitrage ensures that every asset in the economy should plot onto the SML.
- ✓ The positive slope of the SML reflects the fact that investors dislike nondiversifiable risk; the steeper the slope, the greater the dislike.
- ✓ The Fed can shift the entire SML upward or downward by using monetary policy to change the risk-free interest rate on short-term U.S. bonds.

Index Funds versus Actively Managed Funds

Do Actively Managed Funds Outperform Passively Managed Index Funds That Have the Same Risk?

Mutual fund investors have a choice between putting their money into actively managed mutual funds or into passively managed index funds. Actively managed funds constantly buy and sell assets in an attempt to build portfolios that will generate average expected rates of return that are higher than those of other portfolios possessing a similar level of risk. In terms of Figure 37.3, they try to construct portfolios similar to point A, which has the same level of risk as portfolio B but a much higher average expected rate of return. By contrast, the portfolios of index funds simply mimic the assets that are included in their underlying indexes and make no attempt whatsoever to generate higher returns than other portfolios having similar levels of risk.

As a result, expecting actively managed funds to generate higher rates of return than index funds would seem only natural. Surprisingly, however, the exact opposite actually holds true. Once costs are taken into account, the average returns generated by index funds trounce those generated by actively managed funds by well over 1 percent per year. Now, 1 percent per year may not sound like a lot, but the compound interest formula of equation 1 shows that \$10,000 growing for 30 years at 10 percent per year becomes \$170,449.40, whereas that same amount of money growing at 11 percent for 30 years becomes \$220,892.30. For anyone saving for retirement, an extra 1 percent per year is a very big deal.

Why do actively managed funds do so much worse than index funds? The answer is twofold. First, arbitrage makes it virtually impossible for actively managed funds to select portfolios that will do any better than index funds that have similar levels of risk. As a result, *before taking costs into account*, actively managed funds and index funds produce very similar returns. Second, actively managed funds charge their investors much higher fees than do passively managed funds, so that, *after taking costs into account*, actively managed funds do worse by about 1 percent per year.

Let us discuss each of these factors in more detail. The reason that actively managed funds cannot do better than index funds before taking costs into account has to do with the power of arbitrage to ensure that investments having equal levels of risk also have equal average expected rates of return. As we explained above with respect to Figure 37.3, assets and portfolios that deviate from the Security Market Line (SML) are very quickly forced back onto the SML by arbitrage so that assets and portfolios with equal levels of risk have

Source: © Creasource/Corbis

equal average expected rates of return. This implies that index funds and actively managed funds with equal levels of risk will end up with identical average expected rates of return despite the best efforts of actively managed funds to produce superior returns.

The reason actively managed funds charge much higher fees than index funds is because they run up much higher costs while trying to produce superior returns. Not only do they have to pay large salaries to professional fund managers, but they also have to pay for the massive amounts of trading that those managers engage in as they buy and sell assets in their quest to produce superior returns. The costs of running an index fund are, by contrast, very small since changes are made to an index fund's portfolio only on the rare occasions when the fund's underlying index changes. As a result, trading costs are low and there is no need to pay for a professional manager. The overall result is that while the largest and most popular index fund currently charges its investors only 0.17 percent per year for its services, the typical actively managed fund charges about 1.3 percent per year.

So why are actively managed funds still in business? The answer may well be that index funds are boring. Because they are set up to mimic indexes that are in turn designed to show what average performance levels are, index funds are by definition stuck with average rates of return and absolutely no chance to exceed average rates of return. For investors who want to try to beat the average, actively managed funds are the only way to go.

SUMMARY

LO37.1 Define *financial economics* and distinguish between economic investment and financial investment.

Financial investment focuses its attention on investor preferences and how they affect the trading and pricing of the wide variety of financial assets available in the modern economy, including stocks, bonds, and real estate. Remember to distinguish between economic investment (paying for additions to the capital stock) and financial investment (buying an existing asset or building a new asset in the expectation of financial gain).

LO37.2 Explain the time value of money and how compound interest can be used to calculate the present value of any future amount of money.

The compound interest formula states that if X_0 dollars is invested today at interest rate i and allowed to grow for t years, it will become $(1 + i)^t X_0$ dollars in t years. The present value formula rearranges the compound interest formula. It tells investors the current number of dollars that they would have to invest today to receive X_t dollars in t years.

All financial assets available to investors have a common characteristic: In exchange for a certain price today, they all promise to make one or more payments in the future. A risk-free investment's proper current price is simply equal to the sum of the present values of each of the investment's expected future payments.

LO37.3 Identify and distinguish among the most common financial investments: stocks, bonds, and mutual funds.

Stocks give shareholders the right to share in any future profits that corporations may generate. The main risk of stock investing is that future profits are unpredictable and that companies may go bankrupt. Bonds provide bondholders the right to receive a fixed stream of future payments that serve to repay the loan. Bonds are risky because of the possibility that the corporations or government bodies that issued the bonds may default on them, or make less than the promised payments. Mutual funds own and manage portfolios of bonds and stocks; fund investors get the returns generated by those portfolios. The risks of mutual funds to investors reflect the risks of the stocks and bonds that are in their respective portfolios.

LO37.4 Relate how percentage rates of return provide a common framework for comparing assets and explain why asset prices and rates of return are inversely related.

Investors evaluate the possible future returns to risky investments using average expected rates of return, which give higher weight to outcomes that are more likely to happen. Average expected rates of return are inversely related to an asset's current price.

LO37.5 Define and utilize the concept of arbitrage.

Arbitrage is the process whereby investors equalize the average expected rates of return generated by identical or nearly identical assets. If two identical assets have different rates of return, investors will sell the asset with the lower rate of return and buy the asset with

the higher rate of return. As investors buy the asset with the higher rate of return, its price will rise, reducing its average expected rate of return. At the same time, as investors sell the asset with the lower rate of return, its price will fall, raising its average expected rate of return. The process will continue until the average expected rates of return are equal on the two investments.

LO37.6 Describe how the word *risk* is used in financial economics and explain the difference between diversifiable and nondiversifiable risk.

In finance, an asset is risky if its future payments are uncertain. What matters is not whether the payments are big or small, positive or negative, or good or bad—only that they are not guaranteed ahead of time. Risks that can be canceled out by diversification are called diversifiable risks. Risks that cannot be canceled out by diversification are called nondiversifiable risks.

LO37.7 Convey why investment decisions are determined primarily by investment returns and nondiversifiable risk and how investment returns compensate for being patient and for bearing nondiversifiable risk.

Beta is a statistic that measures the nondiversifiable risk of an asset or portfolio relative to the amount of nondiversifiable risk facing the market portfolio. Because the market portfolio contains every asset trading in the financial markets, it is completely diversified and therefore exposed to only nondiversifiable risk. By tradition, its beta is set at 1.0. Thus, an investment that has a beta of 0.5 is exposed to half as much nondiversifiable risk as the market portfolio.

Investors dislike risk and therefore demand compensation for being exposed to it. This compensation takes the form of higher average expected rates of return. The riskier the asset, the greater is the average expected rate of return. Because a well-diversified portfolio has no diversifiable risk, investors will need to be compensated only for the asset's level of nondiversifiable risk as measured by beta.

Average expected rates of return also must compensate for time preference and the fact that, other things equal, people prefer to consume sooner rather than later. Consequently, an asset's average expected rate of return will be the sum of the rate of return that compensates for time preference plus the rate of return that compensates for the asset's level of nondiversifiable risk as measured by beta.

LO37.8 Explain how the Security Market Line illustrates the compensation that investors receive for time preference and nondiversifiable risk and why arbitrage will tend to move all assets onto the Security Market Line.

The rate of return that compensates for time preference is assumed to be equal to the rate of interest generated by short-term U.S. government bonds. These bonds are considered to be risk-free, meaning that their rate of return must purely be compensation for time preference and not nondiversifiable risk.

The Security Market Line (SML) is a straight upsloping line showing how the average expected rates of return on assets and portfolios in the economy vary with their respective levels of

nondiversifiable risk as measured by beta. Arbitrage ensures that every asset in the economy should plot onto the SML. The slope of the SML reflects the investors' dislike for nondiversifiable risk, with steeper slopes reflecting greater dislike for that risk.

The Fed can shift the entire SML upward or downward by using monetary policy to change the risk-free interest rate on short-term

U.S. bonds. When the SML shifts, the average expected rate of return on all assets changes. Because average expected rates of return are inversely related to asset prices, the shift in the SML also will change asset prices. Therefore, the Federal Reserve's ability to change short-run interest rates also enables it to change asset prices throughout the economy.

DISCUSSION QUESTIONS

- Suppose that the city of New York issues bonds to raise money to pay for a new tunnel linking New Jersey and Manhattan. An investor named Susan buys one of the bonds on the same day that the city of New York pays a contractor for completing the first stage of construction. Is Susan making an economic or a financial investment? What about the city of New York? **LO37.1**
- What is compound interest? How does it relate to the formula $X_T = (1 + i)^T X_0$? What is present value? How does it relate to the formula $X/(1 + i)^t = X_0$? **LO37.2**
- How do stocks and bonds differ in terms of the future payments that they are expected to make? Which type of investment (stocks or bonds) is considered to be more risky? Given what you know, which investment (stocks or bonds) do you think commonly goes by the nickname "fixed income"? **LO37.3**
- What are mutual funds? What different types of mutual funds are there? And why do you think they are so popular with investors? **LO37.3**
- Corporations often distribute profits to their shareholders in the form of dividends, which are simply checks mailed out to shareholders. Suppose that you have the chance to buy a share in a fashion company called Rogue Designs for \$35 and that the company will pay dividends of \$2 per year on that share every year. What is the annual percentage rate of return? Next, suppose that you and other investors could get a 12 percent per year rate of return by owning the stocks of other very similar fashion companies. If investors care only about rates of return, what should happen to the share price of Rogue Designs? (Hint: This is an arbitrage situation.) **LO37.5**
- Why is it reasonable to ignore diversifiable risk and care only about nondiversifiable risk? What about investors who put all their money into only a single risky stock? Can they properly ignore diversifiable risk? **LO37.6**
- If we compare the betas of various investment opportunities, why do the assets that have higher betas also have higher average expected rates of return? **LO37.7**
- In this chapter we discussed short-term U.S. government bonds. But the U.S. government also issues longer-term bonds with horizons of up to 30 years. Why do 20-year bonds issued by the U.S. government have lower rates of return than 20-year bonds issued by corporations? And which would you consider more likely, that longer-term U.S. government bonds have a higher interest rate than short-term U.S. government bonds, or vice versa? Explain. **LO37.7**
- What determines the vertical intercept of the Security Market Line (SML)? What determines its slope? And what will happen to an asset's price if it initially plots onto a point above the SML? **LO37.8**
- Suppose that the Federal Reserve thinks that a stock market bubble is occurring and wants to reduce stock prices. What should it do to interest rates? **LO37.8**
- Consider another situation involving the SML. Suppose that the risk-free interest rate stays the same, but that investors' dislike of risk grows more intense. Given this change, will average

expected rates of return rise or fall? Next, compare what will happen to the rates of return on low-risk and high-risk investments. Which will have a larger increase in average expected rates of return, investments with high betas or investments with low betas? And will high-beta or low-beta investments show larger percentage changes in their prices? **L037.8**

12. LAST WORD Why is it so hard for actively managed funds to generate higher rates of return than passively managed index funds having similar levels of risk? Is there a simple way for an actively managed fund to increase its average expected rate of return?

REVIEW QUESTIONS

- Identify each of the following investments as either an economic investment or a financial investment. **L037.1**
 - A company builds a new factory.
 - A pension plan buys some Google stock.
 - A mining company sets up a new gold mine.
 - A woman buys a 100-year-old farmhouse in the countryside.
 - A man buys a newly built home in the city.
 - A company buys an old factory.
- It is a fact that $(1 + 0.12)^3 = 1.40$. Knowing that to be true, what is the present value of \$140 received in three years if the annual interest rate is 12 percent? **L037.2**
 - \$1.40.
 - \$12.
 - \$100.
 - \$112.
- Asset X is expected to deliver 3 future payments. They have present values of, respectively, \$1,000, \$2,000, and \$7,000. Asset Y is expected to deliver 10 future payments, each having a present value of \$1,000. Which of the following statements correctly describes the relationship between the current price of Asset X and the current price of Asset Y? **L037.3**
 - Asset X and Asset Y should have the same current price.
 - Asset X should have a higher current price than Asset Y.
 - Asset X should have a lower current price than Asset Y.
- Tammy can buy an asset this year for \$1,000. She is expecting to sell it next year for \$1,050. What is the asset's anticipated percentage rate of return? **L037.4**
 - 0 percent.
 - 5 percent.
 - 10 percent.
 - 15 percent.
- Sammy buys stock in a suntan-lotion maker and also stock in an umbrella maker. One stock does well when the weather is good; the other does well when the weather is bad. Sammy's portfolio indicates that "weather risk" is a _____ risk. **L037.6**
 - Diversifiable.
 - Nondiversifiable.
 - Automatic.
- An investment has a 50 percent chance of generating a 10 percent return and a 50 percent chance of generating a 16 percent return. What is the investment's average expected rate of return? **L037.7**
 - 10 percent.
 - 11 percent.
 - 12 percent.
 - 13 percent.
 - 14 percent.
 - 15 percent.
 - 16 percent.
- If an investment has 35 percent more nondiversifiable risk than the market portfolio, its beta will be: **L037.7**
 - 35.
 - 1.35.
 - 0.35.
- The interest rate on short-term U.S. government bonds is 4 percent. The risk premium for any asset with a beta = 1.0 is 6 percent. What is the average expected rate of return on the market portfolio? **L037.7**
 - 0 percent.
 - 4 percent.
 - 6 percent.
 - 10 percent.
- Suppose that an SML indicates that assets with a beta = 1.15 should have an average expected rate of return of 12 percent per year. If a particular stock with a beta = 1.15 currently has an average expected rate of return of 15 percent, what should we expect to happen to its price? **L037.8**
 - Rise.
 - Fall.
 - Stay the same.
- If the Fed increases interest rates, the SML will shift _____ and asset prices will _____. **L037.8**
 - Down; rise.
 - Down; fall.
 - Up; rise.
 - Up; fall.

PROBLEMS

- Suppose that you invest \$100 today in a risk-free investment and let the 4 percent annual interest rate compound. Rounded to full dollars, what will be the value of your investment 4 years from now? **L037.2**
- Suppose that you desire to get a lump-sum payment of \$100,000 two years from now. Rounded to full dollars, how many current dollars will you have to invest today at 10 percent interest to accomplish your goal? **L037.2**
- Suppose that a risk-free investment will make three future payments of \$100 in 1 year, \$100 in 2 years, and \$100 in 3 years. If the Federal Reserve has set the risk-free interest rate at 8 percent, what is the proper current price of this investment? What

is the price of this investment if the Federal Reserve raises the risk-free interest rate to 10 percent? **L037.2**

4. Consider an asset that costs \$120 today. You are going to hold it for 1 year and then sell it. Suppose that there is a 25 percent chance that it will be worth \$100 in a year, a 25 percent chance that it will be worth \$115 in a year, and a 50 percent chance that it will be worth \$140 in a year. What is its average expected rate of return? Next, figure out what the investment's average expected rate of return would be if its current price were \$130 today. Does the increase in the current price increase or decrease the asset's average expected rate of return? At what price would the asset have a zero average expected rate of return? **L037.4**
5. Suppose initially that two assets, A and B, will each make a single guaranteed payment of \$100 in 1 year. But asset A has a current price of \$80 while asset B has a current price of \$90. **L037.6**
 - a. What are the rates of return of assets A and B at their current prices? Given these rates of return, which asset should investors buy and which asset should they sell?
 - b. Assume that arbitrage continues until A and B have the same expected rate of return. When arbitrage ends, will A and B have the same price?

Next, consider another pair of assets, C and D. Asset C will make a single payment of \$150 in one year, while D will make a single payment of \$200 in one year. Assume that the current price of C is \$120 and that the current price of D is \$180.

- c. What are the rates of return of assets C and D at their current prices? Given these rates of return, which asset should investors buy and which asset should they sell?
 - d. Assume that arbitrage continues until C and D have the same expected rate of return. When arbitrage ends, will C and D have the same price? Compare your answers to questions *a* through *d* before answering question *e*.
 - e. We know that arbitrage will equalize rates of return. Does it also guarantee to equalize prices? In what situations will it equalize prices?
6. **ADVANCED ANALYSIS** Suppose that the equation for the SML is $Y = 0.05 + 0.04X$, where Y is the average expected rate of return, 0.05 is the vertical intercept, 0.04 is the slope, and X is the risk level as measured by beta. What is the risk-free interest rate for this SML? What is the average expected rate of return at a beta of 1.5? What is the value of beta at an average expected rate of return of 7 percent? **L037.8**

Extending the Analysis of Aggregate Supply

Learning Objectives

- L038.1** Explain the relationship between short-run aggregate supply and long-run aggregate supply.
- L038.2** Discuss how to apply the “extended” (short-run/long-run) AD-AS model to inflation, recessions, and economic growth.
- L038.3** Explain the short-run trade-off between inflation and unemployment (the Phillips Curve).
- L038.4** Discuss why there is no long-run trade-off between inflation and unemployment.
- L038.5** Explain the relationship among tax rates, tax revenues, and aggregate supply.

During the early years of the Great Depression, many economists suggested that the economy would correct itself in the *long run* without government intervention. To this line of thinking, economist John Maynard Keynes remarked, “In the long run we are all dead!”

For several decades following the Great Depression, macroeconomists understandably focused on refining fiscal policy and monetary policy to smooth business cycles and address the problems of unemployment and inflation. The main emphasis was on short-run problems and policies associated with the business cycle.

But over people’s lifetimes, and from generation to generation, the long run is tremendously important for economic well-being. For that reason, macroeconomists have refocused attention on long-run macroeconomic adjustments, processes, and outcomes. The renewed emphasis on the long run has produced significant insights about aggregate supply, economic growth, and economic development. We will also see in the next chapter that it has renewed historical debates over the causes of macro instability and the effectiveness of stabilization policy.

Our goals in this chapter are to extend the analysis of aggregate supply to the long run, examine the inflation-unemployment relationship, and evaluate the effect of taxes on aggregate supply. The latter is a key concern of so-called *supply-side economics*.

From Short Run to Long Run

L038.1 Explain the relationship between short-run aggregate supply and long-run aggregate supply.

In Chapter 32, we noted that in macroeconomics the difference between the **short run** and the **long run** has to do with the flexibility of input prices. Input prices are inflexible or even totally fixed in the short run but fully flexible in the long run. (By contrast, output prices are assumed under these definitions to be fully flexible in both the short run and the long run.)

The assumption that input prices are flexible only in the long run leads to large differences in the shape and position of the short-run aggregate supply curve and the long-run aggregate supply curve. As explained in Chapter 32, the short-run aggregate supply curve is an upsloping line, whereas the long-run aggregate supply curve is a vertical line situated directly above the economy's full-employment output level, Q_f .

We will begin this chapter by discussing how aggregate supply transitions *from* the short run *to* the long run. Once that is done, we will combine the long-run and short-run aggregate supply curves with the aggregate demand curve to form a single model that can provide insights into how the economy adjusts to economic shocks as well as changes in monetary and fiscal policy in both the short run and the long run. That will lead us to discuss how economic growth relates to long-run aggregate supply and how inflation and aggregate supply are related in the long run and the short run. We will conclude with a discussion of a particular set of economic policies that may help increase both short-run aggregate supply and long-run aggregate supply.

Short-Run Aggregate Supply

Our immediate objective is to demonstrate the relationship between short-run aggregate supply and long-run aggregate supply. We begin by briefly reviewing short-run aggregate supply.

Consider the short-run aggregate supply curve AS_1 in Figure 38.1a. This curve is based on three assumptions: (1) The initial price level is P_1 , (2) firms and workers have established nominal wages on the expectation that this price level will persist, and (3) the price level is flexible both upward and downward. Observe from point a_1 that at price level P_1 the economy is operating at its full-employment output Q_f . This output is the real production forthcoming when the economy is operating at its natural rate of unemployment (or potential output).

Now let's review the short-run effects of changes in the price level, say, from P_1 to P_2 in Figure 38.1a. The higher prices associated with price level P_2 increase firms' revenues, and because their nominal wages and other input prices remain unchanged, their profits rise. Those higher profits lead firms to increase their output from Q_f to Q_2 , and the economy moves from a_1 to a_2 on aggregate supply AS_1 . At output Q_2 the economy is operating beyond its full-employment output. The firms make this possible by extending the work hours of part-time and full-time workers, enticing new workers such as homemakers and retirees into the labor force, and hiring and training the structurally unemployed. Thus, the nation's unemployment rate declines below its natural rate.

How will the firms respond when the price level *falls*, say, from P_1 to P_3 in Figure 38.1a? Because the prices they receive

FIGURE 38.1 Short-run and long-run aggregate supply. (a) In the short run, nominal wages and other input prices do not respond to price-level changes and are based on the expectation that price level P_1 will continue. An increase in the price level from P_1 to P_2 increases profits and output, moving the economy from a_1 to a_2 ; a decrease in the price level from P_1 to P_3 reduces profits and real output, moving the economy from a_1 to a_3 . The short-run aggregate supply curve therefore slopes upward. (b) In the long run, a rise in the price level results in higher nominal wages and other input prices and thus shifts the short-run aggregate supply curve to the left. Conversely, a decrease in the price level reduces nominal wages and shifts the short-run aggregate supply curve to the right. After such adjustments, the economy obtains equilibrium of points such as b_1 and c_1 . Thus, the long-run aggregate supply curve is vertical at the full-employment output.

for their products are lower while the nominal wages they pay workers remain unchanged, firms discover that their revenues and profits have diminished or disappeared. So they reduce their production and employment, and, as shown by the movement from a_1 to a_3 , real output falls to Q_3 . Increased unemployment and a higher unemployment rate accompany the decline in real output. At output Q_3 the unemployment rate is greater than the natural rate of unemployment associated with output Q_f .

Long-Run Aggregate Supply

The outcomes are different in the long run. To see why, we need to extend the analysis of aggregate supply to account for changes in nominal wages that occur in response to changes in the price level. That will enable us to derive the economy's long-run aggregate supply curve.

We illustrate the implications for aggregate supply in Figure 38.1b. Again, suppose that the economy is initially at point a_1 (P_1 and Q_f). As we just demonstrated, an increase in the price level from P_1 to P_2 will move the economy from point a_1 to a_2 along the short-run aggregate supply curve AS_1 . At a_2 , the economy is producing at more than its potential output. This implies very high demand for productive inputs, so that input prices will begin to rise. In particular, the high demand for labor will drive up nominal wages, which will increase per unit production costs. As a result, the short-run supply curve shifts leftward from AS_1 to AS_2 , which now reflects the higher price level P_2 and the new expectation that P_2 , not P_1 , will continue. The leftward shift in the short-run aggregate supply curve to AS_2 moves the economy from a_2 to b_1 . Real output falls back to its full-employment level Q_f , and the unemployment rate rises to its natural rate.

What is the long-run outcome of a *decrease* in the price level? Assuming eventual downward wage flexibility, a decline in the price level from P_1 to P_3 in Figure 38.1b works in the opposite way from a price-level increase. At first the economy moves from point a_1 to a_3 on AS_1 . Profits are squeezed or eliminated because prices have fallen and nominal wages have not. But this movement along AS_1 is the short-run supply response that results only while input prices remain constant. As time passes, input prices will begin to fall because the economy is producing at below its full-employment output level. With so little output being produced, the demand for inputs will be low and their prices will begin to decline. In particular, the low demand for labor will drive down nominal wages and reduce per-unit production costs. Lower nominal wages therefore shift the short-run aggregate supply curve rightward from AS_1 to AS_3 , and real output returns to its full-employment level of Q_f at point c_1 .

By tracing a line between the long-run equilibrium points b_1 , a_1 , and c_1 , we obtain a long-run aggregate supply curve. Observe that it is vertical at the full-employment level of real GDP. After long-run adjustments in nominal wages and other

nominal input prices, real output is Q_f regardless of the specific price level.

Long-Run Equilibrium in the AD-AS Model

Figure 38.2 helps us understand the long-run equilibrium in the AD-AS model, now extended to include the distinction between short-run and long-run aggregate supply. (Hereafter, we will refer to this model as the extended AD-AS model, with “extended” referring to the inclusion of both the short-run and the long-run aggregate supply curves.)

In the short run, equilibrium occurs wherever the downsloping aggregate demand curve and upsloping short-run aggregate supply curve intersect. This can be at any level of output, not simply the full-employment level. Either a negative GDP gap or a positive GDP gap is possible in the short run.

But in the long run, the short-run aggregate supply curve adjusts as we just described. After those adjustments, long-run equilibrium occurs where the aggregate demand curve, vertical long-run aggregate supply curve, and short-run aggregate supply curve all intersect. Figure 38.2 shows the long-run outcome. Equilibrium occurs at point a , where AD_1 intersects both AS_{LR} and AS_1 , and the economy achieves its full-employment (or potential) output, Q_f . At long-run equilibrium price level P_1 and output level Q_f , neither a negative GDP gap nor a positive GDP gap occurs. The economy's *natural rate of unemployment* prevails, meaning that the economy achieves full employment.

In the United States, output Q_f in Figure 38.2 implies a 4 to 5 percent unemployment rate. The natural rate of unemployment can vary from one time period to another and can differ between countries. But whatever the rate happens to be, it defines the level of potential output and establishes the location of the long-run AS curve.

FIGURE 38.2 Equilibrium in the long-run AD-AS model. The long-run equilibrium price level P_1 and level of real output Q_f occur at the intersection of the aggregate demand curve AD_1 , the long-run aggregate supply curve AS_{LR} , and the short-run aggregate supply curve AS_1 .

QUICK REVIEW 38.1

- ✓ The short-run aggregate supply curve slopes upward because nominal wages and other input prices are fixed while output prices change.
- ✓ The long-run aggregate supply curve is vertical because input prices eventually rise in response to changes in output prices.
- ✓ The long-run equilibrium GDP and price level occur at the intersection of the aggregate demand curve, the long-run aggregate supply curve, and the short-run aggregate supply curve.
- ✓ In long-run equilibrium, the economy achieves its natural rate of unemployment and its full-potential real output.

Applying the Extended AD-AS Model

LO38.2 Explain how to apply the “extended” (short-run/long-run) AD-AS model to inflation, recessions, and economic growth.

The extended AD-AS model helps clarify the long-run aspects of demand-pull inflation, cost-push inflation, and recession.

Demand-Pull Inflation in the Extended AD-AS Model

Recall that demand-pull inflation occurs when an increase in aggregate demand pulls up the price level. Earlier, we depicted this inflation by shifting an aggregate demand curve rightward along a stable aggregate supply curve (see Figure 32.8).

In our more complex version of aggregate supply, an increase in the price level eventually leads to an increase in nominal wages and thus a leftward shift of the short-run aggregate supply curve. This is shown in Figure 38.3, where we initially suppose the price level is P_1 at the intersection of aggregate demand curve AD_1 , short-run supply curve AS_1 , and long-run aggregate supply curve AS_{LR} . Observe that the economy is achieving its full-employment real output Q_f at point a .

Now consider the effects of an increase in aggregate demand as represented by the rightward shift from AD_1 to AD_2 . This shift might result from any one of a number of factors, including an increase in investment spending or a rise in net exports. Whatever its cause, the increase in aggregate demand boosts the price level from P_1 to P_2 and expands real output from Q_f to Q_2 at point b . There, a positive GDP gap of $Q_2 - Q_f$ occurs.

FIGURE 38.3 Demand-pull inflation in the extended AD-AS model. An increase in aggregate demand from AD_1 to AD_2 drives up the price level and increases real output in the short run. But in the long run, nominal wages rise and the short-run aggregate supply curve shifts leftward, as from AS_1 to AS_2 . Real output then returns to its prior level, and the price level rises even more. In this scenario, the economy moves from a to b and then eventually to c .

So far, none of this is new to you. But now the distinction between short-run aggregate supply and long-run aggregate supply becomes important. With the economy producing above potential output, inputs will be in high demand. Input prices including nominal wages will rise. As they do, the short-run aggregate supply curve will ultimately shift leftward such that it intersects long-run aggregate supply at point c .¹ There, the economy has reestablished long-run equilibrium, with the price level and real output now P_3 and Q_f , respectively. Only at point c does the new aggregate demand curve AD_2 intersect both the short-run aggregate supply curve AS_2 and the long-run aggregate supply curve AS_{LR} .

In the short run, demand-pull inflation drives up the price level and increases real output; in the long run, only the price level rises. In the long run, the initial increase in aggregate demand moves the economy along its vertical aggregate supply curve AS_{LR} . For a while, an economy can operate beyond its full-employment level of output. But the demand-pull inflation eventually causes adjustments of nominal wages that return the economy to its full-employment output Q_f .

¹We say “ultimately” because the initial leftward shift in short-run aggregate supply will intersect the long-run aggregate supply curve AS_{LR} at price level P_2 (review Figure 38.1b). But the intersection of AD_2 and this new short-run aggregate supply curve (that is not shown in Figure 38.3) will produce a price level above P_2 . (You may want to pencil this in to make sure that you understand this point.) Again nominal wages will rise, shifting the short-run aggregate supply curve farther leftward. The process will continue until the economy moves to point c , where the short-run aggregate supply curve is AS_2 , the price level is P_3 , and real output is Q_f .

Cost-Push Inflation in the Extended AD-AS Model

Cost-push inflation arises from factors that increase the cost of production at each price level, shifting the aggregate supply curve leftward and raising the equilibrium price level. Previously (Figure 32.10), we considered cost-push inflation using only the short-run aggregate supply curve. Now we want to analyze that type of inflation in its long-run context.

Analysis Look at Figure 38.4, in which we again assume that the economy is initially operating at price level P_1 and output level Q_f (point a). Suppose that international oil producers agree to reduce the supply of oil to boost its price by, say, 100 percent. As a result, the per-unit production cost of producing and transporting goods and services rises substantially in the economy represented by Figure 38.4. This increase in per-unit production costs shifts the short-run aggregate supply curve to the left, as from AS_1 to AS_2 , and the price level rises from P_1 to P_2 (as seen by comparing points a and b). In this case, the leftward shift of the aggregate supply curve is *not a response* to a price-level increase, as it was in our previous discussions of demand-pull inflation; it is the *initiating cause* of the price-level increase.

Policy Dilemma Cost-push inflation creates a dilemma for policymakers. Without some expansionary stabilization policy, aggregate demand in Figure 38.4 remains in place at AD_1 and real output declines from Q_f to Q_2 . Government can counter this recession, negative GDP gap, and attendant high unemployment by using fiscal policy and monetary policy to

increase aggregate demand to AD_2 . But there is a potential policy trap here: An increase in aggregate demand to AD_2 will further raise inflation by increasing the price level from P_2 to P_3 (a move from point b to point c).

Suppose the government recognizes this policy trap and decides not to increase aggregate demand from AD_1 to AD_2 (you can now disregard the dashed AD_2 curve) and instead decides to allow a cost-push-created recession to run its course. How will that happen? Widespread layoffs, plant shut-downs, and business failures eventually occur. At some point the demand for oil, labor, and other inputs will decline so much that oil prices and nominal wages will decline. When that happens, the initial leftward shift of the short-run aggregate supply curve will reverse itself. That is, the declining per-unit production costs caused by the recession will shift the short-run aggregate supply curve rightward from AS_2 to AS_1 . The price level will return to P_1 , and the full-employment level of output will be restored at Q_f (point a on the long-run aggregate supply curve AS_{LR}).

This analysis yields two generalizations:

- If the government attempts to maintain full employment when there is cost-push inflation, even more inflation will occur.
- If the government takes a hands-off approach to cost-push inflation, the recession will linger. Although falling input prices will eventually undo the initial rise in per-unit production costs, the economy in the meantime will experience high unemployment and a loss of real output.

FIGURE 38.4 Cost-push inflation in the extended AD-AS model. Cost-push inflation occurs when the short-run aggregate supply curve shifts leftward, as from AS_1 to AS_2 . If government counters the decline in real output by increasing aggregate demand to the broken line, the price level rises even more. That is, the economy moves in steps from a to b to c . In contrast, if government allows a recession to occur, nominal wages eventually fall and the aggregate supply curve shifts back rightward to its original location. The economy moves from a to b and eventually back to a .

Recession and the Extended AD-AS Model

By far the most controversial application of the extended AD-AS model is its application to recession (or depression) caused by decreases in aggregate demand. We will look at this controversy in detail in Chapter 39; here we simply identify the key point of contention.

Suppose in Figure 38.5 that aggregate demand initially is AD_1 and that the short-run and long-run aggregate supply curves are AS_1 and AS_{LR} , respectively. Therefore, as shown by point a , the price level is P_1 and output is Q_f . Now suppose that investment spending declines dramatically, reducing aggregate demand to AD_2 . Observe that real output declines from Q_f to Q_1 , indicating that a recession has occurred. But if we make the controversial assumption that prices and wages are flexible downward, the price level falls from P_1 to P_2 . With the economy producing below potential output at point b , demand for inputs will be low. Eventually, nominal wages themselves fall to restore the previous real wage; when that happens, the short-run aggregate supply curve shifts rightward from AS_1 to AS_2 . The negative GDP

FIGURE 38.5 Recession in the extended AD-AS model. A recession occurs when aggregate demand shifts leftward, as from AD_1 to AD_2 . If prices and wages are downwardly flexible, the price level falls from P_1 to P_2 as the economy moves from point a to point b . With the economy in recession at point b , wages eventually fall, shifting the aggregate supply curve from AS_1 to AS_2 . The price level declines to P_3 , and real output returns to Q_f . The economy moves from a to b to c .

gap evaporates without the need for expansionary fiscal or monetary policy since real output expands from Q_1 (point b) back to Q_f (point c). The economy is again located on its long-run aggregate supply curve AS_{LR} , but now at lower price level P_3 .

There is much disagreement about this hypothetical scenario. The key point of dispute revolves around the degree to which both input and output prices may be downwardly inflexible and how long it would take in the actual economy for the necessary downward price and wage adjustments to occur to regain the full-employment level of output. For now, suffice it to say that most economists believe that if such adjustments are forthcoming, they will occur only after the economy has experienced a relatively long-lasting recession with its accompanying high unemployment and large loss of output. The severity and length of the major recession of 2007–2009 has strengthened this view. Therefore, economists recommend active monetary policy, and perhaps fiscal policy, to counteract recessions.

Economic Growth with Ongoing Inflation

In our analysis so far, we have seen how demand and supply shocks can cause, respectively, demand-push inflation and cost-push inflation. But in these previous cases, the extent of the inflation was *finite* because the size of the initial movement in either the AD curve or the AS curve was *limited*. For instance, in Figure 38.3, the aggregate demand curve shifts right by a limited amount, from AD_1 to AD_2 . As the economy's equilibrium moves from a to b to c , the price level rises from P_1 to P_2 to P_3 . During this transition, inflation obviously occurs because the price level is rising. But once the economy

reaches its new equilibrium at point c , the price level remains constant at P_3 and no further inflation takes place. That is, the limited movement in aggregate demand causes a limited amount of inflation that ends when the economy returns to full employment.

But the modern economy almost always experiences continuous, but usually mild, positive rates of inflation. That can only happen with ongoing shifts in either the aggregate demand or long-run aggregate supply curves because any single, finite shift will only cause inflation of limited duration. This insight is crucial to understanding why modern economies usually experience ongoing inflation while achieving economic growth. Both aggregate demand and long-run aggregate supply increase over time in the actual economy, and inflation occurs because the increases in aggregate demand generally exceed the increases in long-run aggregate supply. It will be helpful to examine this point graphically.

Increases in Long-Run Aggregate Supply As discussed in Chapter 28, economic growth is driven by supply factors such as improved technologies and access to more or better resources. Economists illustrate economic growth as either an outward shift of an economy's production possibilities curve or as a rightward shift of its long-run aggregate supply curve. As shown in Figure 38.6, the outward shift of the production possibilities curve from AB to CD in graph a is equivalent to the rightward shift of the economy's long-run aggregate supply curve from AS_{LR1} to AS_{LR2} in graph b .

Let's simply transfer this rightward shift of the economy's long-run aggregate supply curve to Figure 38.7, which depicts economic growth in the United States in the context of the extended aggregate demand–aggregate supply model. Suppose the economy's long-run aggregate supply curve initially is AS_{LR1} , while its aggregate demand curve and short-run aggregate supply curve are AD_1 and AS_1 , as shown. The equilibrium price level is P_1 and the equilibrium level of real output is Q_1 .

Now let's assume that economic growth driven by changes in supply factors (quantity and quality of resources and technology) shifts the long-run aggregate supply curve rightward from AS_{LR1} to AS_{LR2} while the economy's aggregate demand curve remains at AD_1 . Also, suppose that product and resource prices are flexible downward. The economy's potential output will expand, as reflected by the increase of available real output from Q_1 to Q_2 . With aggregate demand constant at AD_1 , the rightward shift of the long-run aggregate supply curve will lower the price level from P_1 to P_3 . Taken alone, expansions of long-run aggregate supply in the economy are deflationary.

Increases in Aggregate Demand and Inflation But a decline in the price level, such as the one from P_1 to P_3 in

FIGURE 38.6 Production possibilities and long-run aggregate supply. (a) Economic growth driven by supply factors (such as improved technologies or the use of more or better resources) shifts an economy's production possibilities curve outward, as from *AB* to *CD*. (b) The same factors shift the economy's long-run aggregate supply curve to the right, as from AS_{LR1} to AS_{LR2} .

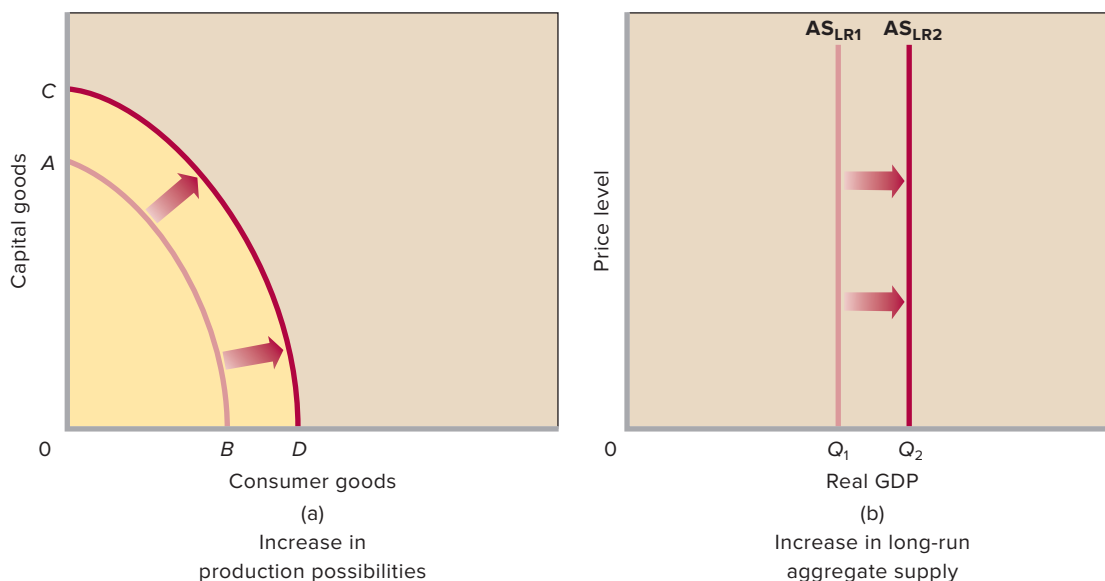

Figure 38.7, is not part of the long-run U.S. growth experience. Why not? The answer is that the nation's central bank—the Federal Reserve—engineers ongoing increases in the nation's money supply to create rightward shifts of the aggregate demand curve. These increases in aggregate demand would be highly inflationary absent the increases in long-run aggregate supply. But because the Fed usually makes sure that the inflationary rightward shifts of the aggregate demand

curve proceed only slightly faster than the deflationary rightward shifts of the aggregate supply curve, only mild inflation occurs along with economic growth.

We illustrate this outcome in Figure 38.7, where aggregate demand shifts to the right from AD_1 to AD_2 at the same time long-run aggregate supply shifts rightward from AS_{LR1} to AS_{LR2} . Real output expands from Q_1 to Q_2 and the price level increases from P_1 to P_2 . At the higher price level P_2 , the

FIGURE 38.7 Depicting U.S. growth via the extended AD-AS model. Long-run aggregate supply and short-run aggregate supply have increased over time, as from AS_{LR1} to AS_{LR2} and AS_1 to AS_2 . Simultaneously, aggregate demand has shifted rightward, as from AD_1 to AD_2 . The actual outcome of these combined shifts has been economic growth, shown as the increase in real output from Q_1 to Q_2 , accompanied by mild inflation, shown as the rise in the price level from P_1 to P_2 .

economy confronts a new short-run aggregate supply curve AS_2 . The changes shown in Figure 38.7 describe the actual U.S. experience: economic growth, accompanied by mild inflation. Real output on average increases at about 3.4 percent annually and inflation averages 2 to 3 percent a year.

Of course, other long-term outcomes besides that depicted are entirely possible. Whether deflation, zero inflation, mild inflation, or rapid inflation accompanies economic growth depends on the extent to which aggregate demand increases relative to long-run aggregate supply. Over long periods, any inflation that accompanies economic growth is exclusively the result of aggregate demand increasing more rapidly than long-run aggregate supply. The expansion of long-run aggregate supply—of potential real GDP—is never the cause of inflation.

QUICK REVIEW 38.2

- ✓ In the short run, demand-pull inflation raises both the price level and real output; in the long run, nominal wages rise, the short-run aggregate supply curve shifts to the left, and only the price level increases.
- ✓ Cost-push inflation creates a policy dilemma for the government: If it engages in an expansionary policy to increase output, additional inflation will occur; if it does nothing, the recession will linger until input prices have fallen by enough to return the economy to producing at potential output.
- ✓ In the short run, a decline in aggregate demand reduces real output (creates a recession); in the long run, prices and nominal wages presumably fall, the short-run aggregate supply curve shifts to the right, and real output returns to its full-employment level.
- ✓ The economy has ongoing inflation because the Fed uses monetary policy to shift the AD curve to the right faster than the supply factors of economic growth shift the long-run AS curve to the right.

The Inflation-Unemployment Relationship

LO38.3 Explain the short-run trade-off between inflation and unemployment (the Phillips Curve).

We have just seen that the Fed can determine how much inflation occurs in the economy by how much it causes aggregate demand to shift relative to aggregate supply. Given that low inflation and low unemployment rates are the Fed's major economic goals, its ability to control inflation brings up at least two interesting policy questions: Are low unemployment and low inflation compatible goals or conflicting goals? What explains situations in which high unemployment and high inflation coexist?

The extended AD-AS model supports three significant generalizations relating to these questions:

- Under normal circumstances, there is a short-run trade-off between the rate of inflation and the rate of unemployment.
- Aggregate supply shocks can cause both higher rates of inflation and higher rates of unemployment.
- There is no significant trade-off between inflation and unemployment over long periods of time.

Let's examine each of these generalizations.

The Phillips Curve

We can demonstrate the short-run trade-off between the rate of inflation and the rate of unemployment through the **Phillips Curve**, named after A. W. Phillips, who developed the idea in Great Britain. This curve, generalized in Figure 38.8a, suggests an inverse relationship between the rate of inflation and the rate of unemployment. Lower unemployment rates (measured as leftward movements on the horizontal axis) are associated with higher rates of inflation (measured as upward movements on the vertical axis).

The underlying rationale of the Phillips Curve becomes apparent when we view the short-run aggregate supply curve in Figure 38.9 and perform a simple mental experiment. Suppose that in some short-run period aggregate demand expands from AD_0 to AD_2 , either because firms decide to buy more capital goods or the government decides to increase its expenditures. Whatever the cause, in the short run the price level rises from P_0 to P_2 and real output rises from Q_0 to Q_2 . As real output rises, the unemployment rate falls.

Now let's compare what would have happened if the increase in aggregate demand had been larger, say, from AD_0 to AD_3 . The equilibrium at P_3 and Q_3 indicates that the amount of inflation and the growth of real output would both have been greater (and that the unemployment rate would have been lower). Similarly, suppose aggregate demand during the year had increased only modestly, from AD_0 to AD_1 . Compared with our shift from AD_0 to AD_2 , the amount of inflation and the growth of real output would have been smaller (and the unemployment rate higher).

The generalization we draw from this mental experiment is this: *Assuming a constant short-run aggregate supply curve*, high rates of inflation are accompanied by low rates of unemployment, and low rates of inflation are accompanied by high rates of unemployment. Other things equal, the expected relationship should look something like Figure 38.8a.

Figure 38.8b reveals that the facts for the 1960s nicely fit the theory. On the basis of that evidence and evidence from other countries, most economists working at the end of the 1960s concluded there was a stable, predictable trade-off between unemployment and inflation. Moreover, U.S. economic

FIGURE 38.8 The Phillips Curve: concept and empirical data. (a) The Phillips Curve relates annual rates of inflation and annual rates of unemployment for a series of years. Because this is an inverse relationship, there presumably is a trade-off between unemployment and inflation. (b) Data points for the 1960s seemed to confirm the Phillips Curve concept. (Note: The unemployment rates are annual averages and the inflation rates are on a December-to-December basis.)

policy was built on that supposed trade-off. According to this thinking, it was impossible to achieve “full employment without inflation”: Manipulation of aggregate demand through fiscal and monetary measures would simply move the economy along the Phillips Curve. An expansionary fiscal and monetary policy that boosted aggregate demand and lowered the unemployment rate would simultaneously increase inflation. A restrictive fiscal and monetary policy could be used to reduce the

rate of inflation but only at the cost of a higher unemployment rate and more forgone production. Society had to choose between the incompatible goals of price stability and full employment; it had to decide where to locate on its Phillips Curve.

FIGURE 38.9 The short-run effect of changes in aggregate demand on real output and the price level. Comparing the effects of various possible increases in aggregate demand leads to the conclusion that the larger the increase in aggregate demand, the higher the rate of inflation and the greater the increase in real output. Because real output and the unemployment rate move in opposite directions, we can generalize that, given short-run aggregate supply, high rates of inflation should be accompanied by low rates of unemployment.

For reasons we will soon see, today’s economists reject the idea of a stable, predictable Phillips Curve. Nevertheless, they agree there is a short-run trade-off between unemployment and inflation. *Given short-run aggregate supply*, increases in aggregate demand increase real output and reduce the unemployment rate. As the unemployment rate falls and dips below the natural rate, the excessive spending produces demand-pull inflation. Conversely, when recession sets in and the unemployment rate increases, the weak aggregate demand that caused the recession also leads to lower inflation rates.

Periods of exceptionally low unemployment rates and inflation rates do occur, but only under special sets of economic circumstances. One such period was the late 1990s, when faster productivity growth increased aggregate supply and fully blunted the inflationary impact of rapidly rising aggregate demand (review Figure 32.11).

Aggregate Supply Shocks and the Phillips Curve

The unemployment-inflation experience of the 1970s and early 1980s demolished the idea of an always-stable Phillips Curve. In Figure 38.10, we show the Phillips Curve for the 1960s in blue and then add the data points for 1970 through 2015. Observe that in most of the years of the 1970s and early 1980s, the economy experienced both higher inflation rates

FIGURE 38.10 Inflation rates and unemployment rates, 1960–2015. A series of aggregate supply shocks in the 1970s resulted in higher rates of inflation *and* higher rates of unemployment. So data points for the 1970s and 1980s tended to be above and to the right of the blue Phillips Curve for the 1960s. In the 1990s, the inflation-unemployment data points slowly moved back toward the 1960s Phillips Curve. Points for the late 1990s and 2000s are similar to those from the 1960s. However, the data point for 2009 (9.3 percent unemployment, –0.4 percent inflation) was located dramatically lower and much farther to the right relative to the data point for 2008 (5.8 percent unemployment, 3.8 percent inflation). That movement reflected negative inflation accompanied by much higher unemployment during 2009. As the economy slowly mended after the Great Recession, the data points for 2011 through 2015 (highlighted in blue) showed inflation and unemployment falling simultaneously—a pattern inconsistent with moving along a single fixed Philips curve.

and higher unemployment rates than it did in the 1960s. In fact, inflation and unemployment rose simultaneously in some of those years. This condition is called **stagflation**—a media term that combines the words “stagnation” and “inflation.” If there still was any such thing as a Phillips Curve, it had clearly shifted outward, perhaps as shown.

Adverse Aggregate Supply Shocks The data points for the 1970s and early 1980s support our second generalization: Aggregate supply shocks can cause both higher rates of inflation and higher rates of unemployment. A series of adverse **aggregate supply shocks**—sudden, large increases in resource costs that jolt an economy’s short-run aggregate supply curve leftward—hit the economy in the 1970s and early 1980s. The most significant of these shocks was a quadrupling of oil prices by the Organization of Petroleum Exporting Countries (OPEC). Consequently, the cost of producing and distributing virtually every product and service rose rapidly.

(Other factors working to increase U.S. costs during this period included major agricultural shortfalls, a greatly depreciated dollar, wage hikes previously held down by wage-price controls, and slower rates of productivity growth.)

These shocks shifted the aggregate supply curve to the left and distorted the usual inflation-unemployment relationship. Remember that we derived the inverse relationship between the rate of inflation and the unemployment rate shown in Figure 38.8a by shifting the aggregate demand curve along a stable short-run aggregate supply curve (Figure 38.9). But the cost-push inflation model shown in Figure 38.4 tells us that a *leftward shift* of the short-run aggregate supply curve increases the price level and reduces real output (and increases the unemployment rate). This, say most economists, is what happened in two periods in the 1970s. The U.S. unemployment rate shot up from 4.9 percent in 1973 to 8.5 percent in 1975, contributing to a significant decline in real GDP. In the same period, the U.S. price level rose by 21 percent. The

stagflation scenario recurred in 1978, when OPEC increased oil prices by more than 100 percent. The U.S. price level rose by 26 percent over the 1978–1980 period, while unemployment increased from 6.1 to 7.2 percent.

Stagflation's Demise Another look at Figure 38.10 reveals a generally inward movement of the inflation-unemployment points between 1982 and 1989. By 1989, the lingering effects of the earlier period had subsided. One precursor to this favorable trend was the deep recession of 1981–1982, largely caused by a restrictive monetary policy aimed at reducing double-digit inflation. The recession upped the unemployment rate to 9.7 percent in 1982. With so many workers unemployed, those who were working accepted smaller increases in their nominal wages—or, in some cases, wage reductions—in order to preserve their jobs. Firms, in turn, restrained their price increases to try to retain their relative shares of a greatly diminished market.

Other factors were at work. Foreign competition throughout this period held down wage and price hikes in several basic industries such as automobiles and steel. Deregulation of the airline and trucking industries also resulted in wage reductions or so-called wage givebacks. A significant decline in OPEC's monopoly power and a greatly reduced reliance on oil in the production process produced a stunning fall in the price of oil and its derivative products, such as gasoline.

All these factors combined to reduce per-unit production costs and to shift the short-run aggregate supply curve rightward (as from AS_2 to AS_1 in Figure 38.4). Employment and output expanded, and the unemployment rate fell from 9.6 percent in 1983 to 5.3 percent in 1989. Figure 38.10 reveals that the inflation-unemployment points for the late 1990s and 2000s are closer to the points associated with the Phillips Curve of the 1960s than to the points that plot out the data for the late 1970s and early 1980s.

The 2007–2009 recession led to shifts in unemployment and inflation that were inconsistent with a stable Phillips curve. In 2008, unemployment was still at a historically moderate 5.8 percent while inflation came in at 3.8 percent. The inflation-unemployment point for 2009, however, moved down and to the right significantly as unemployment jumped to 9.3 percent while the inflation rate fell to a deflationary -0.4 percent. The point for 2010 moved a bit up and to the right as unemployment peaked at 9.6 percent and inflation rose to 1.6 percent. Then the 2011 point moved up and to the left as unemployment began to fall and inflation rose to 3.2 percent. As the economy continued to mend, the points for 2012 through 2015 moved down and to the left as the economy experienced an ongoing pattern of falling inflation coinciding with falling unemployment—a pattern inconsistent with moving along a single fixed Phillips Curve.

The media sometimes express the sum of the unemployment rate and the inflation rate as a rough gauge of the

economic discomfort that inflation and unemployment jointly impose on an economy in a particular year. The sum of the two rates is used to compute the *misery index*. For example, a nation with a 5 percent unemployment rate and a 5 percent inflation rate has a misery index number of 10, as does a nation with an 8 percent unemployment rate and a 2 percent inflation rate.

Global Perspective 38.1 shows the misery index for several nations between 2004 and 2014. (It uses average annual inflation rates, not the December-to-December inflation rates used to construct Figure 38.10.) The U.S. misery index number has been neither exceptionally low nor exceptionally high relative to the misery index numbers for the other major economies shown. But bear in mind that economists do not put much stock in the misery index because they do not view the national discomfort associated with a 1 percent change in inflation and a 1 percent change in unemployment as necessarily equivalent. In particular, the misery index can greatly disguise the extent of hardship during a recession. The rise in the unemployment rate in these circumstances causes a huge loss of national output and income (and misery!), even if the higher unemployment rate is partially or fully offset with a decline in the rate of inflation.

The Long-Run Phillips Curve

L038.4 Discuss why there is no long-run trade-off between inflation and unemployment.

The overall set of data points in Figure 38.10 supports our third generalization relating to the inflation-unemployment relationship: There is no apparent *long-run* trade-off between inflation and unemployment. Economists point out that when decades (as opposed to a few years) are considered, any rate of inflation is consistent with the natural rate of unemployment prevailing at that time. We know from Chapter 29 that the natural rate of unemployment is the unemployment rate that occurs when cyclical unemployment is zero; it is the full-employment rate of unemployment, or the rate of unemployment when the economy achieves its potential output.

How can there be a short-run inflation-unemployment trade-off but not a long-run trade-off? Figure 38.11 provides the answer.

Short-Run Phillips Curve

Consider Phillips Curve PC_1 in Figure 38.11. Suppose the economy initially is experiencing a 3 percent rate of inflation

FIGURE 38.11 The long-run vertical Phillips Curve. Increases in aggregate demand beyond those consistent with full-employment output may temporarily boost profits, output, and employment (as from a_1 to b_1). But nominal wages eventually will catch up so as to sustain real wages. When they do, profits will fall, negating the previous short-run stimulus to production and employment (the economy now moves from b_1 to a_2). Consequently, there is no trade-off between the rates of inflation and unemployment in the long run; that is, the long-run Phillips Curve is roughly a vertical line at the economy's natural rate of unemployment.

and a 5 percent natural rate of unemployment. Such short-term curves as PC_1 , PC_2 , and PC_3 (drawn as straight lines for simplicity) exist because the actual rate of inflation is not always the same as the expected rate.

Establishing an additional point on Phillips Curve PC_1 will clarify this. We begin at a_1 , where we assume nominal wages are set on the assumption that the 3 percent rate of inflation will continue. That is, because workers expect output prices to rise by 3 percent per year, they negotiate wage contracts that feature 3 percent per year increases in nominal wages so that these nominal wage increases will exactly offset the expected rise in prices and thereby keep their real wages the same.

But suppose that the rate of inflation rises to 6 percent, perhaps because the Fed has decided to move the AD curve to the right even faster than it had been before. With a nominal wage rate set on the expectation that the 3 percent rate of inflation will continue, the higher product prices raise business profits. Firms respond to the higher profits by hiring more workers and increasing output. In the short run, the economy moves to b_1 , which, in contrast to a_1 , involves a lower rate of unemployment (4 percent) and a higher rate of inflation (6 percent). The move from a_1 to b_1 is consistent both with an upsloping aggregate supply curve and with the inflation-unemployment trade-off implied by the Phillips Curve analysis. But this short-run Phillips Curve simply is a manifestation of the following principle: *When the actual rate of inflation is higher than expected, profits temporarily rise and the unemployment rate temporarily falls.*

Long-Run Vertical Phillips Curve

But point b_1 is not a stable equilibrium. Workers will recognize that their nominal wages have not increased as fast as inflation and will therefore renegotiate their labor contracts so that they feature faster increases in nominal wages. These faster increases in nominal wages make up for the higher rate of inflation and restore the workers' lost purchasing power. As these new labor contracts kick in, business profits will fall to their prior level. The reduction in profits means that the original motivation to employ more workers and increase output has disappeared.

Unemployment then returns to its natural level at point a_2 . Note, however, that the economy now faces a higher actual and expected rate of inflation—6 percent rather than 3 percent. This happens because the new labor contracts feature 6 percent per year increases in wages to make up for the 6 percent per year inflation rate. Because wages are a production cost, this faster increase in wage rates will imply faster future increases in output prices as firms are forced to raise prices more rapidly to make up for the faster future rate of wage growth. Stated a bit differently, the initial increase in inflation will become *persistent* because it leads to renegotiated

labor contracts that will perpetuate the higher rate of inflation. In addition, because the new labor contracts are public, it will also be the case that the higher rates of inflation that they will cause will be *expected* by everyone rather than being a surprise.

In view of the higher 6 percent expected rate of inflation, the short-run Phillips Curve shifts upward from PC_1 to PC_2 in Figure 38.11. An “along-the-Phillips-Curve” kind of move from a_1 to b_1 on PC_1 is merely a short-run or transient occurrence. In the long run, after nominal wage contracts catch up with increases in the inflation rate, unemployment returns to its natural rate at a_2 , and there is a new short-run Phillips Curve PC_2 at the higher expected rate of inflation.

The scenario repeats if aggregate demand continues to increase. Prices rise momentarily ahead of nominal wages, profits expand, and employment and output increase (as implied by the move from a_2 to b_2). But, in time, nominal wages increase so as to restore real wages. Profits then fall to their original level, pushing employment back to the normal rate at a_3 . The economy’s “reward” for lowering the unemployment rate below the natural rate is a still higher (9 percent) rate of inflation.

Movements along the short-run Phillips curve (a_1 to b_1 on PC_1) cause the curve to shift to a less favorable position (PC_2 , then PC_3 , and so on). A stable Phillips Curve with the dependable series of unemployment-rate–inflation-rate trade-offs simply does not exist in the long run. The economy is characterized by a **long-run vertical Phillips Curve**.

The vertical line through a_1 , a_2 , and a_3 shows the long-run relationship between unemployment and inflation. Any rate of inflation is consistent with the 5 percent natural rate of unemployment. So, in this view, society ought to choose a low rate of inflation rather than a high one.

Disinflation

The distinction between the short-run Phillips Curve and the long-run Phillips Curve also helps explain **disinflation**—reductions in the inflation rate from year to year. Suppose that in Figure 38.11 the economy is at a_3 , where the inflation rate is 9 percent. And suppose that a decline in the rate at which aggregate demand shifts to the right faster than aggregate supply (as happened during the 1981–1982 recession) reduces inflation below the 9 percent expected rate, say, to 6 percent. Business profits fall because prices are rising less rapidly than wages. The nominal wage increases, remember, were set on the assumption that the 9 percent rate of inflation would continue. In response to the decline in profits, firms reduce their employment and consequently the unemployment rate rises. The economy temporarily slides downward from point a_3 to c_3 along the short-run Phillips Curve PC_3 . *When the actual rate of inflation is lower than the expected rate, profits temporarily fall and the unemployment rate temporarily rises.*

Firms and workers eventually adjust their expectations to the new 6 percent rate of inflation, and thus newly negotiated wage increases decline. Profits are restored, employment rises, and the unemployment rate falls back to its natural rate of 5 percent at a_2 . Because the expected rate of inflation is now 6 percent, the short-run Phillips Curve PC_3 shifts leftward to PC_2 .

If the rate at which aggregate demand shifts to the right faster than aggregate supply declines even more, the scenario will continue. Inflation declines from 6 percent to, say, 3 percent, moving the economy from a_2 to c_2 along PC_2 . The lower-than-expected rate of inflation (lower prices) squeezes profits and reduces employment. But, in the long run, firms respond to the lower profits by reducing their nominal wage increases. Profits are restored and unemployment returns to its natural rate at a_1 as the short-run Phillips Curve moves from PC_2 to PC_1 . Once again, the long-run Phillips Curve is vertical at the 5 percent natural rate of unemployment.

QUICK REVIEW 38.3

- ✓ As implied by the upsloping short-run aggregate supply curve, there may be a short-run trade-off between the rate of inflation and the rate of unemployment. This trade-off is reflected in the Phillips Curve, which shows that lower rates of inflation are associated with higher rates of unemployment.
- ✓ Aggregate supply shocks that produce severe cost-push inflation can cause stagflation—simultaneous increases in the inflation rate and the unemployment rate. Such stagflation occurred from 1973–1975 and recurred from 1978–1980, producing Phillips Curve data points above and to the right of the Phillips Curve for the 1960s.
- ✓ After all nominal wage adjustments to increases and decreases in the rate of inflation have occurred, the economy ends up back at its full-employment level of output and its natural rate of unemployment. The long-run Phillips Curve therefore is vertical at the natural rate of unemployment.

Taxation and Aggregate Supply

L038.5 Explain the relationship among tax rates, tax revenues, and aggregate supply.

A final topic in our discussion of aggregate supply is taxation, a key aspect of **supply-side economics**. “Supply-side economists” or “supply-siders” stress that changes in aggregate supply are an active force in determining the levels of inflation, unemployment, and economic growth. Government policies can either impede or promote rightward shifts of the short-run and long-run aggregate supply curves shown in Figure 38.2. One such policy is taxation.

These economists say that the enlargement of the U.S. tax system has impaired incentives to work, save, and invest. In this view, high tax rates impede productivity growth and hence slow the expansion of long-run aggregate supply. By reducing the after-tax rewards of workers and producers, high tax rates reduce the financial attractiveness of working, saving, and investing.

Supply-siders focus their attention on *marginal tax rates*—the rates on extra dollars of income—because those rates affect the benefits from working, saving, or investing more. In 2016, marginal federal income tax rates varied from 10 to 39.6 percent in the United States.

Taxes and Incentives to Work

Supply-siders believe that how long and how hard people work depends on the amounts of additional after-tax earnings they derive from their efforts. They say that lower marginal tax rates on earned incomes induce more work, and therefore increase aggregate inputs of labor. Lower marginal tax rates increase the after-tax wage rate and make leisure more expensive and work more attractive. The higher opportunity cost of leisure encourages people to substitute work for leisure. This increase in productive effort is achieved in many ways: by increasing the number of hours worked per day or week, by encouraging workers to postpone retirement, by inducing more people to enter the labor force, by motivating people to work harder, and by avoiding long periods of unemployment.

Incentives to Save and Invest

High marginal tax rates also reduce the rewards for saving and investing. For example, suppose that Tony saves \$10,000 at 8 percent interest, bringing him \$800 of interest per year. If his marginal tax rate is 40 percent, his after-tax interest earnings will be \$480, not \$800, and his after-tax interest rate will fall to 4.8 percent. While Tony might be willing to save (forgo current consumption) for an 8 percent return on his saving, he might rather consume when the return is only 4.8 percent.

Saving, remember, is the prerequisite of investment. Thus, supply-side economists recommend lower marginal tax rates on interest earned from saving. They also call for lower taxes on income from capital to ensure that there are ready investment outlets for the economy's enhanced pool of saving. A critical determinant of investment spending is the expected *after-tax* return on that spending.

To summarize: Lower marginal tax rates encourage saving and investing. Workers therefore find themselves equipped with more and technologically superior machinery and equipment. Labor productivity rises, and that expands long-run aggregate supply and economic growth, which in turn keeps unemployment rates and inflation low.

The Laffer Curve

In the supply-side view, reductions in marginal tax rates increase the nation's aggregate supply and can leave the nation's tax revenues unchanged or even enlarge them. Thus, supply-side tax cuts need not produce federal budget deficits.

This idea is based on the **Laffer Curve**, named after Arthur Laffer, who popularized it. As Figure 38.12 shows, the Laffer Curve depicts the relationship between tax rates and tax revenues. As tax rates increase from 0 to 100 percent, tax revenues increase from zero to some maximum level (at m) and then fall to zero. Tax revenues decline beyond some point because higher tax rates discourage economic activity, thereby shrinking the tax base (domestic output and income). This is easiest to see at the extreme, where the tax rate is 100 percent. Tax revenues here are, in theory, reduced to zero because the 100 percent confiscatory tax rate has halted production. A 100 percent tax rate applied to a tax base of zero yields no revenue.

In the early 1980s, Laffer suggested that the United States was at a point such as n on the curve in Figure 38.12. At n , tax rates are so high that production is discouraged to the extent that tax revenues are below the maximum at m . If the economy is at n , then lower tax rates can either increase tax revenues or leave them unchanged. For example, lowering the tax rate from point n to point l would bolster the economy such that the government would bring in the same total amount of tax revenue as before.

Laffer's reasoning was that lower tax rates stimulate incentives to work, save and invest, innovate, and accept business risks, thus triggering an expansion of real output and income. That enlarged tax base sustains tax revenues even though tax rates are lowered. Indeed, between n and m lower tax rates result in *increased* tax revenue.

FIGURE 38.12 The Laffer Curve. The Laffer Curve suggests that up to point m higher tax rates will result in larger tax revenues. But tax rates higher than m will adversely affect incentives to work and produce, reducing the size of the tax base (output and income) to the extent that tax revenues will decline. It follows that if tax rates are above m , reductions in tax rates will produce increases in tax revenues.

Also, when taxes are lowered, tax avoidance (which is legal) and tax evasion (which is not) decline. High marginal tax rates prompt taxpayers to avoid taxes through various tax shelters, such as buying municipal bonds, on which the interest earned is tax-free. High rates also encourage some taxpayers to conceal income from the Internal Revenue Service. Lower tax rates reduce the inclination to engage in either tax avoidance or tax evasion.

The Laffer curve also implies that for any particular amount of tax revenue that the government can possibly collect, there will be both a high tax rate at which that amount of revenue can be collected as well as a low tax rate at which that amount of revenue can be collected. As an example, compare points n and l in Figure 38.12. Point n has a high tax rate and point l has a low tax rate, but they both collect the same amount of tax revenue. So if the government's major goal when setting tax rates is simply to collect a particular total amount of tax revenue, Laffer argued that the government should always opt for the lower tax rate. By doing so, the government would collect the revenue it desired while imposing as little as possible on the private economy.

Criticisms of the Laffer Curve

The Laffer Curve and its supply-side implications have been subject to severe criticism.

Taxes, Incentives, and Time A fundamental criticism relates to the degree to which economic incentives are sensitive to changes in tax rates. Skeptics say ample empirical evidence shows that the impact of a tax cut on incentives is small, of uncertain direction, and relatively slow to emerge. For example, with respect to work incentives, studies indicate that decreases in tax rates lead some people to work more but lead others to work less. Those who work more are enticed by the higher after-tax pay; they substitute work for leisure because the opportunity cost of leisure has increased. But other people work less because the higher after-tax pay enables them to “buy more leisure.” With the tax cut, they can earn the same level of after-tax income as before with fewer work hours.

Inflation or Higher Real Interest Rates Most economists think that the demand-side effects of a tax cut are more immediate and certain than longer-term supply-side effects. Thus, tax cuts undertaken when the economy is at or near full employment may produce increases in aggregate demand that overwhelm any increase in aggregate supply. The likely result is inflation or restrictive monetary policy to prevent it. If the latter, real interest rates will rise and investment will decline. This will defeat the purpose of the supply-side tax cuts.

Position on the Curve Skeptics say that the Laffer Curve is merely a logical proposition and assert that there must be some

Sherwood Forest

The popularization of the idea that tax-rate reductions may increase tax revenues owes much to Arthur Laffer's ability to present his ideas simply. He reportedly took out his pen and drew a curve on a napkin to illustrate his tax ideas to a *Wall Street Journal* editor. The editor retained the napkin and later reproduced the curve in an editorial in

The Wall Street Journal. The Laffer Curve was born and the idea it portrayed became the centerpiece of economic policy under the Reagan administration (1981–1989), which cut tax rates on personal income by 25 percent over a three-year period.

Laffer illustrated his supply-side views with a story relating to Robin Hood, who, you may recall, stole from the rich to give to the poor. Laffer likened people traveling through Sherwood Forest to taxpayers, whereas Robin Hood and his band of merry men were government. As taxpayers passed through the forest, Robin Hood and his men intercepted them and forced them to hand over their money. Laffer asked audiences, “Do you think that travelers continued to go through Sherwood Forest?”

The answer he sought and got, of course, was “no.” Taxpayers will avoid Sherwood Forest to the greatest extent possible. They will lower their taxable income by reducing work hours, retiring earlier, saving less, and engaging in tax avoidance and tax evasion activities. Robin Hood and his men may end up with less revenue than if they collected a relatively small “tax” from each traveler for passage through the forest.

level of tax rates between 0 and 100 percent at which tax revenues will be at their maximum. Economists of all persuasions can agree with this. But the issue of where a particular economy is located on its Laffer Curve is an empirical question. If we assume that we are at point n in Figure 38.12, then tax cuts will increase tax revenues. But if the economy is at any point below m on the curve, tax-rate reductions will reduce tax revenues.

Rebuttal and Evaluation

Supply-side advocates respond to the skeptics by contending that the Reagan tax cuts in the 1980s worked as Laffer predicted. Although the top marginal income tax rates on earned income were cut from 50 to 28 percent in that decade, real GDP and tax revenues were substantially higher at the end of the 1990s than at the beginning.

Do Tax Increases Reduce Real GDP?*

Determining the Relationship between Changes in Taxes and Permanent Changes in Real GDP Is Fraught with Complexities and Difficulties. University of California-Berkeley Economists Christina Romer and David Romer Have Recently Devised a Novel Way to Approach the Topic. Their Findings Suggest That Tax Increases Reduce Real GDP.†

How do changes in the level of taxation affect the level of economic activity? The simple correlation between taxation and economic activity shows that, on average, when economic activity rises more rapidly, tax revenues also are rising more rapidly. But this correlation almost surely does not reflect a positive effect of tax increases on output. Rather, under our tax system, any positive shock to output raises tax revenues by increasing income.

In “The Macroeconomic Effects of Tax Changes: Estimates Based on a New Measure of Fiscal Shocks,” authors Christina Romer and David Romer observe that this difficulty is just one of many manifestations of a more general problem. Changes in taxes occur for many reasons. And, because the factors that give rise to tax changes often are correlated with other developments in the economy, disentangling the effects of the tax changes from the other effects of these underlying factors is inherently difficult.

To address this problem, Romer and Romer use the narrative record—presidential speeches, executive branch documents, congressional reports, and so on—to identify the size, timing, and principal motivation for all major tax policy actions in the post–World War II United States. This narrative analysis allows them to separate revenue changes resulting from legislation from changes occurring for other reasons. It also allows them to classify legislated changes according to their primary motivation.

Romer and Romer find that despite the complexity of the legislative process, most significant tax changes have been motivated by one of four factors: counteracting other influences in the economy; paying for increases in government spending (or lowering taxes in conjunction with reductions in spending); addressing an inherited budget deficit; and promoting long-run growth. They observe that legislated tax changes taken to counteract other influences on the economy, or to pay for increases in government spending, are very

likely to be correlated with other factors affecting the economy. As a result, these observations are likely to lead to unreliable estimates of the effect of tax changes.

Tax changes that are made to promote long-run growth, or to reduce an inherited budget deficit, in contrast, are undertaken for reasons essentially unrelated to other factors influencing output. Thus, examining the behavior of output following these tax changes is likely to provide more reliable estimates of the output effects of tax changes. *The results of this more reliable test indicate that tax changes have very large effects: a tax increase of 1 percent of GDP lowers real GDP by roughly 2 to 3 percent.*

These output effects are highly persistent. The behavior of inflation and unemployment suggests that this persistence reflects long-lasting departures of output from previous levels. Romer and Romer also find that output effects of tax changes are much more closely tied to the actual changes in taxes than news about future

changes, and that investment falls sharply in response to tax changes. Indeed, the strong response of investment helps to explain why the output consequences of tax increases are so large.

Romer and Romer find suggestive evidence that tax increases to reduce an inherited budget deficit have much smaller output costs than other tax increases. This is consistent with the idea that deficit-driven tax increases may have important expansionary effects through [improved] expectations and [lower] long-term interest rates, or through [enhanced] confidence.

But the general view among economists is that the Reagan tax cuts, coming at a time of severe recession, helped boost aggregate demand and return real GDP to its full-employment output and normal growth path. As the economy expanded, so did tax revenues despite the lower tax rates. The rise in tax revenues caused by economic growth swamped the declines in revenues from lower tax rates. In essence, the Laffer Curve shown in Figure 38.12 stretched rightward, increasing net tax revenues. But the tax-rate cuts did not produce extraordinary rightward shifts of the long-run aggregate supply curve. Indeed, saving fell as a percentage of personal income during the period and productivity growth was sluggish. Real GDP sprang back vigorously from recessionary levels, but the economic growth rate soon reverted back to its longer-term average.

Because government expenditures rose more rapidly than tax revenues in the 1980s, large budget deficits occurred. In 1993 the Clinton administration increased the top marginal tax rates from 31 to 39.6 percent to address these deficits. The economy boomed in the last half of the 1990s, and by the end of the decade, tax revenues were so high relative to government expenditures that budget surpluses emerged. In 2001 the Bush administration reduced marginal tax rates over a series of years, partially “to return excess revenues to taxpayers.” In 2003 the top marginal tax rate fell to 35 percent. Also, the income tax rates on capital gains and dividends were reduced to 15 percent. Economists generally agree that the Bush tax cuts, along with a highly expansionary monetary policy, helped revive and expand the economy following the recession of 2001. Strong growth of output and income in 2004 and 2005 produced large increases in tax revenues, although large budget deficits remained because spending also increased rapidly. The 2004 deficit was \$413 billion and the 2005 deficit was \$318 billion. The deficit fell over the next two years, to \$162 billion in 2007. But the previously discussed financial crisis plunged the economy into a severe recession beginning in December 2007 and lasting into 2009. That caused income to fall and tax revenues to plummet. Also, the government aggressively pursued expansionary fiscal policy. Budget deficits increased to \$459 billion in 2008

and \$1.4 trillion in 2009. They decreased in subsequent years, down to around \$445 billion in 2015.

Today, there is general agreement that the U.S. economy is operating at a point below m —rather than above m —on the Laffer Curve in Figure 38.12. In this zone, the overall effect is that personal tax-rate increases raise tax revenues while personal tax-rate decreases reduce tax revenues. But at the same time, economists recognize that, other things being equal, cuts in tax rates reduce tax revenues in percentage terms by less than the tax-rate reductions. Similarly, tax-rate increases do not raise tax revenues by as much in percentage terms as the tax-rate increases. This is true because changes in marginal tax rates alter taxpayer behavior and thus affect taxable income. Although these effects seem to be relatively modest, they need to be considered in designing tax policy—and, in fact, the federal government’s Office of Tax Policy created a special division in 2007 devoted to estimating the magnitude of such effects when it comes to proposed changes in U.S. tax laws. Thus, supply-side economics has contributed to how economists and policymakers design and implement fiscal policy.

SUMMARY

LO38.1 Explain the relationship between short-run aggregate supply and long-run aggregate supply.

In macroeconomics, the short run is a period in which nominal wages do not respond to changes in the price level. In contrast, the long run is a period in which nominal wages fully respond to changes in the price level.

The short-run aggregate supply curve is upsloping. Because nominal wages are unresponsive to price-level changes, increases

in the price level (prices received by firms) increase profits and real output. Conversely, decreases in the price level reduce profits and real output. However, the long-run aggregate supply curve is vertical. With sufficient time for adjustment, nominal wages rise and fall with the price level, moving the economy along a vertical aggregate supply curve at the economy’s full-employment output.

L038.2 Discuss how to apply the “extended” (short-run/long-run) AD-AS model to inflation, recessions, and economic growth.

In the short run, demand-pull inflation raises the price level and real output. Once nominal wages rise to match the increase in the price level, the temporary increase in real output is reversed.

In the short run, cost-push inflation raises the price level and lowers real output. Unless the government expands aggregate demand, nominal wages will eventually decline under conditions of recession and the short-run aggregate supply curve will shift back to its initial location. Prices and real output will eventually return to their original levels.

If prices and wages are flexible downward, a decline in aggregate demand will lower output and the price level. The decline in the price level will eventually lower nominal wages and shift the short-run aggregate supply curve rightward. Full-employment output will thus be restored.

One-time changes in aggregate demand (AD) and aggregate supply (AS) can only cause limited bouts of inflation. Ongoing mild inflation occurs because the Fed purposely increases AD slightly faster than the expansion of long-run AS (driven by the supply factors of economic growth).

L038.3 Explain the short-run trade-off between inflation and unemployment (the Phillips Curve).

Assuming a stable, upsloping short-run aggregate supply curve, rightward shifts of the aggregate demand curve of various sizes yield the generalization that high rates of inflation are associated with low rates of unemployment, and vice versa. This inverse relationship is known as the Phillips Curve, and empirical data for the 1960s seemed to be consistent with it.

In the 1970s and early 1980s, the Phillips Curve apparently shifted rightward, reflecting stagflation—simultaneously rising inflation rates and unemployment rates. The higher unemployment

rates and inflation rates resulted mainly from huge oil price increases that caused large leftward shifts in the short-run aggregate supply curve (so-called aggregate supply shocks). The Phillips Curve shifted inward toward its original position in the 1980s. By 1989, stagflation had subsided, and the data points for the late 1990s and first half of the first decade of the 2000s were similar to those of the 1960s. The new pattern continued until 2009, when the unemployment rate jumped to 9.3 percent while the inflation rate plummeted to a negative 0.4 percent.

As the economy slowly recovered, unemployment and inflation fell simultaneously between 2011 and 2015—a pattern inconsistent with the economy moving along a single fixed Phillips Curve.

L038.4 Discuss why there is no long-run trade-off between inflation and unemployment.

Although there is a short-run trade-off between inflation and unemployment, there is no long-run trade-off. Workers will adapt their expectations to new inflation realities, and when they do, the unemployment rate will return to the natural rate. So the long-run Phillips Curve is vertical at the natural rate, meaning that higher rates of inflation do not permanently “buy” the economy less unemployment.

L038.5 Explain the relationship among tax rates, tax revenues, and aggregate supply.

Supply-side economists focus attention on government policies, such as high taxation, that impede the expansion of aggregate supply. The Laffer Curve relates tax rates to levels of tax revenue and suggests that under some circumstances, cuts in tax rates will expand the tax base (output and income) and increase tax revenues. Most economists, however, believe that the United States is currently operating in the range of the Laffer Curve where tax rates and tax revenues move in the same, not opposite, direction.

Today’s economists recognize the importance of considering supply-side effects in designing optimal fiscal policy.

- L039.4** Summarize the fundamental ideas and policy implications of mainstream macroeconomics, monetarism, and rational expectations theory.

As any academic discipline evolves, it naturally evokes a number of internal disagreements. Economics is no exception. In this chapter we examine a few alternative perspectives on macro theory and policy. We focus on the disagreements that various economists have about the answers to three interrelated questions: (1) What causes instability in the economy? (2) Is the economy self-correcting?

(3) Should government adhere to *rules* or use *discretion* in setting economic policy?

What Causes Macro Instability?

L039.1 Describe alternative perspectives on the causes of macroeconomic instability, including the views of mainstream economists, monetarists, real-business-cycle advocates, and proponents of coordination failures.

As earlier chapters have indicated, capitalist economies experienced considerable instability during the twentieth century. The United States, for example, experienced the Great Depression, numerous recessions, and periods of inflation. This instability greatly moderated between the early 1980s and 2007, but then the deep recession of 2007–2009 occurred. Economists have different perspectives about why instability like this happens.

Mainstream View

For simplicity, we will use the term “mainstream view” to characterize the prevailing macroeconomic perspective of the majority of economists. According to that view, instability in the economy arises from two sources: (1) price stickiness and (2) unexpected shocks to either aggregate demand or aggregate supply.

As we explained in detail in Chapter 38, in the long run, when both input and output prices are fully flexible and have time to adjust to any changes in aggregate demand or short-run

aggregate supply, the economy will always return to producing at potential output. In the shorter run, however, stickiness in either input or output prices will mean that any shock to either aggregate demand or aggregate supply will result in changes in output and employment. Although they are not new to you, let's quickly review shocks to aggregate demand and aggregate supply.

Changes in Aggregate Demand Mainstream macroeconomics focuses on aggregate spending and its components. Recall that the basic equation underlying aggregate expenditures is

$$C_a + I_g + X_n + G = \text{GDP}$$

That is, the aggregate amount of after-tax consumption, gross investment, net exports, and government spending determines the total amount of goods and services produced and sold. In equilibrium, $C_a + I_g + X_n + G$ (aggregate expenditures) is equal to GDP (real output). A decrease in the price level increases equilibrium GDP and thus allows us to trace out a downsloping aggregate demand curve for the economy (see the appendix to Chapter 32). Any change in one of the spending components in the aggregate expenditures equation shifts the aggregate demand curve. This, in turn, changes equilibrium real output, the price level, or both.

Investment spending in particular is subject to wide “booms” and “busts.” Significant increases in investment spending are multiplied into even greater increases in aggregate demand and thus can produce demand-pull inflation. In contrast, significant declines in investment spending are multiplied into even greater decreases in aggregate demand and thus can cause recessions.

Adverse Aggregate Supply Shocks In the mainstream view, the second source of macroeconomic instability arises on the supply side. Occasionally, such external events as wars or an artificial supply restriction of a key resource can boost resource prices and significantly raise per-unit production costs. The result is a sizable decline in a nation's aggregate supply, which destabilizes the economy by simultaneously causing cost-push inflation and recession.

Monetarist View

Monetarism (1) focuses on the money supply, (2) holds that markets are highly competitive, and (3) says that a competitive market system gives the economy a high degree of macroeconomic stability. Monetarists argue that the price and wage flexibility provided by competitive markets should cause fluctuations in aggregate demand to alter product and resource prices rather than output and employment. Thus, the market system would provide substantial macroeconomic stability *were it not for government interference in the economy.*

The problem, as monetarists see it, is that government has promoted downward wage inflexibility through the minimum-wage law, pro-union legislation, guaranteed prices for certain farm products, pro-business monopoly legislation, and so forth. The free-market system is capable of providing macroeconomic stability, but, despite good intentions, government interference has undermined that capability. Moreover, monetarists say that government has contributed to the economy's business cycles through its clumsy and mistaken attempts to achieve greater stability through its monetary policies.

Equation of Exchange The fundamental equation of monetarism is the **equation of exchange**:

$$MV = PQ$$

where M is the supply of money; V is the **velocity** of money, that is, the average number of times per year a dollar is spent on final goods and services; P is the price level or, more specifically, the average price at which each unit of physical output is sold; and Q is the physical volume of all goods and services produced.

The left side of the equation of exchange, MV , represents the total amount spent by purchasers of output, while the right side, PQ , represents the total amount received by sellers of that output. The nation's money supply (M) multiplied by the number of times it is spent each year (V) must equal the nation's nominal GDP ($= P \times Q$). The dollar value of total spending has to equal the dollar value of total output.

Stable Velocity Monetarists say that velocity, V , in the equation of exchange is relatively stable. To them, “stable” is not synonymous with “constant,” however. Monetarists are aware that velocity has generally trended upward over the last several decades. Shorter pay periods, widespread use of credit cards, and faster means of making payments enable people to hold less money and to turn it over more rapidly than was possible in earlier times. These factors have enabled people to reduce their holdings of cash and checkbook money relative to the size of the nation's nominal GDP.

When monetarists say that velocity is stable, they mean that the factors altering velocity change gradually and predictably and that changes in velocity from one year to the next can be readily anticipated. Moreover, they hold that velocity does not change in response to changes in the money supply itself. Instead, people have a stable desire to hold money relative to holding other financial assets, holding real assets, and buying current output. The factors that determine the amount of money the public wants to hold depend mainly on the level of nominal GDP.

Example: Assume that when the level of nominal GDP is \$400 billion, the public desires \$100 billion of money to

purchase that output. That means that V is 4 (= \$400 billion of nominal GDP/\$100 billion of money). If we further assume that the actual supply of money is \$100 billion, the economy is in equilibrium with respect to money; the actual amount of money supplied equals the amount the public wants to hold.

If velocity is stable, the equation of exchange suggests that there is a predictable relationship between the money supply and nominal GDP (= PQ). An increase in the money supply of, say, \$10 billion would upset equilibrium in our example since the public would find itself holding more money or liquidity than it wants. That is, the actual amount of money held (\$110 billion) would exceed the amount of holdings desired (\$100 billion). In that case, the reaction of the public (households and businesses) is to restore its desired balance of money relative to other items, such as stocks and bonds, factories and equipment, houses and automobiles, and clothing and toys. But the spending of money by individual households and businesses would leave more cash in the checkable deposits or billfolds of other households and firms. And they too would try to “spend down” their excess cash balances. But, overall, the \$110 billion supply of money cannot be spent down because a dollar spent is a dollar received.

Instead, the collective attempt to reduce cash balances increases aggregate demand, thereby boosting nominal GDP. Because velocity in our example is 4—that is, the dollar is spent, on average, four times per year—nominal GDP rises from \$400 billion to \$440 billion. At that higher nominal GDP, the money supply of \$110 billion equals the amount of money desired (\$440 billion/4 = \$110 billion), and equilibrium is reestablished.

The \$10 billion increase in the money supply thus eventually increases nominal GDP by \$40 billion. Spending on goods, services, and assets expands until nominal GDP has gone up enough to restore the original 4-to-1 equilibrium relationship between nominal GDP and the money supply.

Note that the relationship GDP/M defines V . A stable relationship between nominal GDP and M means a stable V . And a change in M causes a proportionate change in nominal GDP. Thus, monetarists say that changes in the money supply have a predictable effect on nominal GDP (= $P \times Q$). An increase in M increases P or Q , or some combination of both; a decrease in M reduces P or Q , or some combination of both.

Monetary Causes of Instability Monetarists say that inappropriate monetary policy is the single most important cause of macroeconomic instability. An increase in the money supply directly increases aggregate demand. Under conditions of full employment, that rise in aggregate demand raises the price level. For a time, higher prices cause firms to increase their real output, and the rate of unemployment falls below its natural rate. But once nominal wages rise to reflect

the higher prices and thus to restore real wages, real output moves back to its full-employment level and the unemployment rate returns to its natural rate. The inappropriate increase in the money supply leads to inflation, together with instability of real output and employment.

Conversely, a decrease in the money supply reduces aggregate demand. Real output temporarily falls, and the unemployment rate rises above its natural rate. Eventually, nominal wages fall and real output returns to its full-employment level. The inappropriate decline in the money supply leads to deflation, together with instability of real GDP and employment.

The contrast between mainstream macroeconomics and monetarism on the causes of instability thus comes into sharp focus. Mainstream economists view the instability of investment as the main cause of the economy’s instability. They see monetary policy as a stabilizing factor. Changes in the money supply raise or lower interest rates as needed, smooth out swings in investment, and thus reduce macroeconomic instability. In contrast, monetarists view changes in the money supply as the main cause of instability in the economy. For example, they say that the Great Depression occurred largely because the Fed allowed the money supply to fall by roughly one-third during that period. According to Milton Friedman, a prominent monetarist,

And [the money supply] fell not because there were no willing borrowers—not because the horse would not drink. It fell because the Federal Reserve System forced or permitted a sharp reduction in the [money supply], because it failed to exercise the responsibilities assigned to it in the Federal Reserve Act to provide liquidity to the banking system. The Great Contraction is tragic testimony to the power of monetary policy—not, as Keynes and so many of his contemporaries believed, evidence of its impotence.¹

Real-Business-Cycle View

A third modern view of the cause of macroeconomic instability is that business cycles are caused by real factors that affect aggregate supply rather than by monetary, or spending, factors that cause fluctuations in aggregate demand. In the **real-business-cycle theory**, business fluctuations result from significant changes in technology and resource availability. Those changes affect productivity and thus the long-run growth trend of aggregate supply.

An example focusing on recession will clarify this thinking. Suppose productivity (output per worker) declines sharply because of a large increase in oil prices, which makes it prohibitively expensive to operate certain types of machinery. That decline in productivity implies a reduction in the economy’s ability to produce real output. The result would be

¹Milton Friedman, *The Optimum Quantity of Money and Other Essays* (Chicago: Aldine, 1969), p. 97.

FIGURE 39.1 The real-business-cycle theory. In the real-business-cycle theory, a decline in resource availability shifts the nation's long-run aggregate supply curve to the left from AS_{LR1} to AS_{LR2} . The decline in real output from Q_1 to Q_2 , in turn, reduces money demand (less is needed) and money supply (fewer loans are taken out) such that aggregate demand shifts leftward from AD_1 to AD_2 . The result is a recession in which the price level remains constant.

a decrease in the economy's long-run aggregate supply curve, as represented by the leftward shift from AS_{LR1} to AS_{LR2} in Figure 39.1.

As real output falls from Q_1 to Q_2 , the public needs less money to buy the reduced volume of goods and services. So the demand for money falls. Moreover, the slowdown in business activity means that businesses need to borrow less from banks, reducing the part of the money supply created by banks through their lending. Thus, the supply of money also falls. In this controversial scenario, changes in the supply of money respond to changes in the demand for money. The decline in the money supply then reduces aggregate demand, as from AD_1 to AD_2 in Figure 39.1. The outcome is a decline in real output from Q_1 to Q_2 , with no change in the price level.

Conversely, a large increase in aggregate supply (not shown) caused by, say, major innovations in the production process would shift the long-run aggregate supply curve rightward. Real output would increase, and money demand and money supply would both increase. Aggregate demand would shift rightward by an amount equal to the rightward shift of long-run aggregate supply. Real output would increase, without driving up the price level.

Conclusion: In the real-business-cycle theory, macro instability arises on the aggregate supply side of the economy, not on the aggregate demand side as mainstream economists and monetarists usually claim.

Too Much Money?

The severe recession of 2007–2009 fits the mainstream view that recessions are caused by AD shocks rather than the real-business-cycle view that they are caused by AS shocks. Recall that the recession began with a financial crisis that caused significant reductions in investment spending and consumption spending and therefore reduced aggregate demand. As inventories increased, businesses further curtailed their investment

spending, and aggregate demand, output, and income dropped even more.

Economists with monetarist leanings, however, cite monetary factors as the main cause of the financial crisis that led to the initial declines in aggregate demand. They argue that the Federal Reserve flooded the economy with too much money and held interest rates too low for too long in promoting recovery from the 2001 recession. In this line of reasoning, the excess money and low interest rates contributed to the bubble in the housing market. When that bubble burst, the resulting loan defaults set in motion the forces that produced the declines in AD and therefore the recession.

All economists agree that the bursting of the housing bubble led to the recession. And too-loose monetary policy may have contributed to the bubble. But economists also cite the role of the very large international flows of foreign savings into the United States during this period. These inflows drove down interest rates and helped to fuel the housing bubble. Other factors such as “pass-the-risk” lending practices, government policies promoting home ownership, and poorly designed and enforced financial regulations certainly came into play. The mainstream view is that causes of the financial crisis and recession are numerous and complex.

Coordination Failures

A fourth and final modern view of macroeconomic instability relates to so-called **coordination failures**. Such failures occur when people fail to reach a mutually beneficial equilibrium because they lack a way to coordinate their actions.

Noneconomic Example Consider first a noneconomic example. Suppose you hear that some people might be

getting together at the last minute for an informal party at a nearby beach. But because of a chance of rain, there is some doubt about whether people will actually come out. You make a cell phone call or two to try to get a read on what others are thinking, and then base your decision on that limited information. If you expect others to be there, you will decide to go. If you expect that no one will go, you will decide to stay home. There are several possible equilibrium outcomes, depending on the mix of people's expectations. Let's consider just two. If each person assumes that all the others will go to the party, all will go. The party will occur and presumably everyone will have a good time. But if each person assumes that everyone else will stay home, all will stay home and there will be no party. When the party does not take place, even though all would be better off if it did take place, a coordination failure has occurred.

Macroeconomic Example Now let's apply this example to macroeconomic instability, specifically recession. Suppose that individual firms and households expect other firms and consumers to cut back their investment and consumption spending. As a result, each firm and household will anticipate a reduction of aggregate demand. Firms therefore will reduce their own investment spending since they will anticipate that their future production capacity will be excessive. Households will also reduce their own spending (increase their saving) because they anticipate that they will experience reduced work hours, possible layoffs, and falling incomes in the future.

Aggregate demand will indeed decline and the economy will indeed experience a recession in response to what amounts to a self-fulfilling prophecy. Moreover, the economy will stay at a below-full-employment level of output because, once there, producers and households have no individual incentive to increase spending. If all producers and households would agree to increase their investment and consumption spending simultaneously, then aggregate demand would rise, and real output and real income would increase. Each producer and each consumer would be better off. However, this outcome does not occur because there is no mechanism for firms and households to agree on such a joint spending increase.

In this case, the economy is stuck in an *unemployment equilibrium* because of a coordination failure. With a different set of expectations, a coordination failure might leave the economy in an *inflation equilibrium*. In this view, the economy has a number of such potential equilibrium positions, some good and some bad, depending on people's mix of expectations. Macroeconomic instability, then, reflects the movement of the economy from one such equilibrium position to another as expectations change.

QUICK REVIEW 39.1

- ✓ Mainstream economists say that macroeconomic instability usually stems from swings in investment spending and, occasionally, from adverse aggregate supply shocks.
- ✓ Monetarists view the economy through the equation of exchange ($MV = PQ$). If velocity V is stable, changes in the money supply M lead directly to changes in nominal GDP ($P \times Q$). For monetarists, changes in M caused by inappropriate monetary policy are the single most important cause of macroeconomic instability.
- ✓ In the real-business-cycle theory, significant changes in "real" factors such as technology, resource availability, and productivity change the economy's long-run aggregate supply, causing macroeconomic instability.
- ✓ Macroeconomic instability can result from coordination failures—less-than-optimal equilibrium positions that occur because businesses and households lack a way to coordinate their actions.

Does the Economy "Self-Correct"?

L039.2 Discuss why new classical economists believe the economy will "self-correct" from aggregate demand and aggregate supply shocks.

Just as there are disputes over the causes of macroeconomic instability, there are disputes over whether or not the economy will correct itself when instability does occur. And economists also disagree on how long it will take for any such self-correction to take place.

New Classical View of Self-Correction

New classical economists tend to be either monetarists or adherents of **rational expectations theory**: the idea that businesses, consumers, and workers expect changes in policies or circumstances to have certain effects on the economy and, in pursuing their own self-interest, take actions to make sure those changes affect them as little as possible. The **new classical economics** holds that when the economy occasionally diverges from its full-employment output, internal mechanisms within the economy will automatically move it back to that output. Policymakers should stand back and let the automatic correction occur, rather than engage in active fiscal and monetary policy. This perspective is often associated with the vertical long-run Phillips Curve, which we discussed in Chapter 38. But we will analyze it here using the extended AD-AS model that was also developed in Chapter 38.

FIGURE 39.2 New classical view of self-correction. (a) An unanticipated increase in aggregate demand from AD_1 to AD_2 first moves the economy from a to b . The economy then self-corrects to c . An anticipated increase in aggregate demand moves the economy directly from a to c . (b) An unanticipated decrease in aggregate demand from AD_1 to AD_3 moves the economy from a to d . The economy then self-corrects to e . An anticipated decrease in aggregate demand moves the economy directly from a to e . (Mainstream economists, however, say that if the price level remains at P_1 , the economy will move from a to f , and even if the price level falls to P_4 , the economy may remain at d because of downward wage inflexibility.)

Graphical Analysis Figure 39.2a relates the new classical analysis to the question of self-correction. Specifically, an increase in aggregate demand, say, from AD_1 to AD_2 , moves the economy upward along its short-run aggregate supply curve AS_1 from a to b . The price level rises and real output increases. With the economy producing beyond potential output, high resource demand drives up the prices of labor and other productive inputs. Per-unit production costs increase and the short-run aggregate supply curve shifts leftward, eventually from AS_1 to AS_2 . The economy moves from b to c , and real output returns to its full-employment level, Q_1 . This level of output is dictated by the economy's vertical long-run aggregate supply curve, AS_{LR} .

Conversely, a decrease in aggregate demand from AD_1 to AD_3 in Figure 39.2b first moves the economy downward along its short-run aggregate supply curve AS_1 from point a to d . The price level declines, as does the level of real output. With the economy producing below potential output, low resource demand drives down the prices of labor and other productive inputs. When that happens, per-unit production costs decline and the short-run aggregate supply curve shifts to the right, eventually from AS_1 to AS_3 . The economy moves to e , where it again achieves its full-employment level, Q_1 . As in Figure 39.2a, the economy in Figure 39.2b has automatically self-corrected to its full-employment output and its natural rate of unemployment.

Speed of Adjustment There is some disagreement among new classical economists on how long it will take for self-correction to occur. Monetarists usually hold the *adaptive expectations* view that people form their expectations on the

basis of present realities and only gradually change their expectations as experience unfolds. This means that the shifts in the short-run aggregate supply curves shown in Figure 39.2 may not occur for two or three years or even longer. Other new classical economists, however, accept the rational expectations assumption that workers anticipate some future outcomes before they occur. When price-level changes are fully anticipated, adjustments of nominal wages are very quick or even instantaneous. Let's see why.

Although several new theories incorporate rational expectations, our interest here is the new classical version of the rational expectations theory (hereafter, RET). RET is based on two assumptions:

- People behave rationally, gathering and intelligently processing information to form expectations about things that are economically important to them. They adjust those expectations quickly as new developments affecting future economic outcomes occur. Where there is adequate information, people's beliefs about future economic outcomes accurately reflect the likelihood that those outcomes will occur. For example, if it is clear that a certain policy will cause inflation, people will recognize that fact and adjust their economic behavior in anticipation of inflation.
- RET economists assume that all product and resource markets are highly competitive and that prices and wages are flexible both upward and downward. But the RET economists go further, assuming that new information is quickly (in some cases, instantaneously) taken into account in the demand and supply curves of such markets.

The upshot is that equilibrium prices and quantities adjust rapidly to unforeseen events—say, technological change or aggregate supply shocks. They adjust instantaneously to events that have known outcomes—for example, changes in fiscal or monetary policy.

Unanticipated Price-Level Changes The implication of RET is not only that the economy is self-correcting but that self-correction occurs quickly. In this thinking, unanticipated changes in the price level—so-called **price-level surprises**—do cause temporary changes in real output. Suppose, for example, that an unanticipated increase in foreign demand for U.S. goods increases U.S. aggregate demand from AD_1 to AD_2 in Figure 39.2a. The immediate result is an unexpected increase in the price level from P_1 to P_2 .

But now an interesting question arises. If wages and prices are flexible, as assumed in RET, why doesn't the higher price level immediately cause wages and other input prices to rise, such that there is no increase in real output at all? Why does the economy temporarily move from point a to b along AS_1 ? In RET, firms increase output from Q_1 to Q_2 because of misperceptions about rising prices of their own products relative to the prices of other products (and to the prices of labor). They mistakenly think the higher prices of their own products have resulted from increased demand for those products relative to the demands for other products. Expecting higher profits, they increase their own production. But in fact *all* prices, including the price of labor (nominal wages), are rising because of the general increase in aggregate demand. Once firms see that *all* prices and wages are rising, they decrease their production to previous levels.

In terms of Figure 39.2a, the increase in nominal wages shifts the short-run aggregate supply curve leftward, ultimately from AS_1 to AS_2 , and the economy moves from b to c . Thus, the increase in real output caused by the price-level surprise corrects itself.

The same analysis in reverse applies to an unanticipated price-level decrease. In the economy represented by Figure 39.2b, firms misperceive that the prices of their own products are falling due to decreases in the demand for those products relative to other products. They incorrectly anticipate declines in profit and cut production. As a result of their collective actions, real output in the economy falls. Once firms see what is really happening—that *all* prices and wages are dropping—they increase their output to prior levels. The short-run aggregate supply curve in Figure 39.2b shifts rightward from AS_1 to AS_3 , and the economy “self-corrects” by moving from d to e .

Fully Anticipated Price-Level Changes In RET, fully *anticipated* price-level changes do not change real output, even for short periods. In Figure 39.2a, again consider the increase in aggregate demand from AD_1 to AD_2 . Businesses

immediately recognize that the higher prices being paid for their products are part of the inflation they had anticipated. They understand that the same forces that are causing the inflation result in higher nominal wages, leaving their profits unchanged. The economy therefore moves directly from a to c . The price level rises as expected, and output remains at its full-employment level Q_1 .

Similarly, a fully *anticipated* price-level decrease will leave real output unchanged. Firms conclude that nominal wages are declining by the same percentage amount as the declining price level, leaving profits unchanged. The economy represented by Figure 39.2b therefore moves directly from a to e . Deflation occurs, but the economy continues to produce its full-employment output Q_1 . The anticipated decline in aggregate demand causes no change in real output.

Mainstream View of Self-Correction

Almost all economists acknowledge that the new classical economists have made significant contributions to the theory of aggregate supply. In fact, mainstream economists have incorporated some aspects of RET into their own models. However, most economists strongly disagree with RET on the question of downward price and wage flexibility. While the stock market, foreign exchange market, and certain commodity markets experience day-to-day or minute-to-minute price changes, including price declines, that is not true of many product markets and most labor markets. There is ample evidence, say mainstream economists, that many prices and wages are inflexible downward for long periods. As a result, it may take years for the economy to move from recession back to full-employment output, unless it gets help from fiscal and monetary policy.

Graphical Analysis To understand this mainstream view, again examine Figure 39.2b. Suppose aggregate demand declines from AD_1 to AD_3 because of a significant decline in investment spending. If prices are sticky downward for a while and therefore the price level is temporarily stuck at P_1 , the economy will not move from a to d to e , as suggested by RET. Instead, the economy will move from a to f , as if it were moving along the white horizontal P_1 price line between those two points. Real output will decline from its full-employment level, Q_1 , to the recessionary level, Q_4 .

But let's assume that large amounts of unsold inventories eventually cause the price level to fall to P_4 . Will this lead to the decline in nominal wages needed to shift aggregate supply from AS_1 to AS_3 , as suggested by the new classical economists? “Highly unlikely” say mainstream economists. Even more so than prices, nominal wages tend to be inflexible downward. If nominal wages do not decline in response to the decline in the price level, then the short-run aggregate supply curve will not shift rightward. The self-correction mechanism assumed by

RET and new classical economists will break down. Instead, the economy will remain at d , experiencing less-than-full-employment output and a high rate of unemployment.

Downward Wage Inflexibility In Chapter 32 we discussed several reasons why firms may not be able to, or may not want to, lower nominal wages. Firms may not be able to cut wages because of wage contracts and the legal minimum wage. And firms may not want to lower wages if they fear potential problems with morale, effort, and efficiency.

While contracts are thought to be the main cause of wage rigidity, so-called efficiency wages and insider-outsider relationships also may play a role. Let's explore both.

Efficiency Wage Theory Recall from Chapter 32 that an **efficiency wage** is a wage that minimizes the firm's labor cost per unit of output. Normally, we would think that the market wage is the efficiency wage since it is the lowest wage at which a firm can obtain a particular type of labor. But where the cost of supervising workers is high or where worker turnover is great, firms may discover that paying a wage that is higher than the market wage will lower their wage cost per unit of output.

Example: Suppose a firm's workers, on average, produce 8 units of output at a \$9 market wage but 10 units of output at a \$10 above-market wage. The efficiency wage is \$10, not the \$9 market wage. At the \$10 wage, the labor cost per unit of output is only \$1 ($= \$10 \text{ wage}/10 \text{ units of output}$), compared with \$1.12 ($= \$9 \text{ wage}/8 \text{ units of output}$) at the \$9 wage.

How can a higher wage result in greater efficiency?

- **Greater work effort** The above-market wage, in effect, raises the cost to workers of losing their jobs as a result of poor performance. Because workers have a strong incentive to retain their relatively high-paying jobs, they are more likely to provide greater work effort. Looked at differently, workers are more reluctant to shirk (neglect or avoid work) because the higher wage makes job loss more costly to them. Consequently, the above-market wage can be the efficient wage; it can enhance worker productivity so much that the higher wage more than pays for itself.
- **Lower supervision costs** With less incentive among workers to shirk, the firm needs fewer supervisory personnel to monitor work performance. This, too, can lower the firm's overall wage cost per unit of output.
- **Reduced job turnover** The above-market pay discourages workers from voluntarily leaving their jobs. The lower turnover rate reduces the firm's cost of hiring and training workers. It also gives the firm a more experienced, more productive workforce.

The key implication for macroeconomic instability is that efficiency wages add to the downward inflexibility of wages. Firms that pay efficiency wages will be reluctant to cut wages when aggregate demand declines, since such cuts may

encourage shirking, require more supervisory personnel, and increase turnover. In other words, wage cuts that reduce productivity and raise per-unit labor costs are self-defeating.

Insider-Outsider Relationships Other economists theorize that downward wage inflexibility may relate to relationships between "insiders" and "outsiders." Insiders are workers who retain employment even during recession. Outsiders are workers who have been laid off from a firm and unemployed workers who would like to work at that firm.

When recession produces layoffs and widespread unemployment, we might expect outsiders to offer to work for less than the current wage rate, in effect, bidding down wage rates. We also might expect firms to hire such workers to reduce their costs. But, according to the **insider-outsider theory**, outsiders may not be able to underbid existing wages because employers may view the nonwage cost of hiring them to be prohibitive. Employers might fear that insiders would view acceptance of such underbidding as undermining years of effort to increase wages or, worse, as "stealing" jobs. So insiders may refuse to cooperate with new workers who have undercut their pay. Where teamwork is critical for production, such lack of cooperation will reduce overall productivity and thereby lower the firms' profits.

Even if firms are willing to employ outsiders at less than the current wage, those workers might refuse to work for less than the existing wage. To do so might invite harassment from the insiders whose pay they have undercut. Thus, outsiders may remain unemployed, relying on past saving, unemployment compensation, and other social programs to make ends meet.

As in the efficiency wage theory, the insider-outsider theory implies that wages will be inflexible downward when aggregate demand declines. Self-correction may eventually occur but not nearly as rapidly as the new classical economists contend.

QUICK REVIEW 39.2

- ✓ New classical economists believe that the economy "self-corrects" when unanticipated events divert it from its full-employment level of real output.
- ✓ In RET, unanticipated price-level changes cause changes in real output in the short run but not in the long run.
- ✓ According to RET, market participants immediately change their actions in response to anticipated price-level changes such that no change in real output occurs.
- ✓ Mainstream economists say that the economy can get mired in recession for several months or more because of downward price and wage inflexibility.
- ✓ Sources of downward wage inflexibility include contracts, efficiency wages, and insider-outsider relationships.

Rules or Discretion?

L039.3 Identify and describe the variations of the debate over “rules” versus “discretion” in conducting stabilization policy.

These different views on the causes of instability and on the speed of self-correction have led to vigorous debate on macro policy. Should the government adhere to policy rules that prohibit it from causing instability in an economy that is otherwise stable? Or should it use discretionary fiscal and monetary policy, when needed, to stabilize a sometimes-unstable economy?

In Support of Policy Rules

Monetarists and other new classical economists believe policy rules would reduce instability in the economy. They believe that such rules would prevent government from trying to “manage” aggregate demand. That would be a desirable trend because, in their view, such management is misguided and thus is likely to *cause* more instability than it cures.

Monetary Rule Since inappropriate monetary policy is the major source of macroeconomic instability, say monetarists, the enactment of a **monetary rule** would make sense. One such rule would be a requirement that the Fed expand the money supply each year at the same annual rate as the typical growth of the economy’s production capacity. That fixed-rate expansion of the money supply would occur whatever the state of the economy. The Fed’s sole monetary role would be to use its tools (open-market operations, the discount rate, interest on reserves, and reserve requirements) to ensure that the nation’s money supply grew steadily by, say, 3 to 5 percent a year. According to Milton Friedman,

Such a rule . . . would eliminate . . . the major cause of instability in the economy—the capricious and unpredictable impact of countercyclical monetary policy. As long as the money supply grows at a constant rate each year, be it 3, 4, or 5 percent, any decline into recession will be temporary. The liquidity provided by a constantly growing money supply will cause aggregate demand to expand. Similarly, if the supply of money does not rise at a more than average rate, any inflationary increase in spending will burn itself out for lack of fuel.²

Figure 39.3 illustrates the rationale for a monetary rule. Suppose the economy represented there is operating at its full-employment real output, Q_1 . Also suppose the nation’s long-run aggregate supply curve shifts rightward, as from AS_{LR1} to AS_{LR2} , each year, signifying the average annual increase in potential real output. As you saw in earlier chapters, such annual increases in “potential GDP” result from added resources, improved resources, and improved technology.

On the Road Again

Economist Abba Lerner (1903–1982) likened the economy to an automobile traveling down a road that had traffic barriers on each side. The problem was that the car had no steering wheel. It would hit

one barrier, causing the car to veer to the opposite side of the road. There it would hit the other barrier, which in turn would send it careening to the opposite side. To avoid such careening in the form of business cycles, said Lerner, society must equip the economy with a steering wheel. Discretionary fiscal and monetary policy would enable government to steer the economy safely between the problems of recession and demand-pull inflation.

Economist Milton Friedman (1912–2006) modified Lerner’s analogy, giving it a different meaning. He said that the economic vehicle does not need a skillful driver who is continuously turning the wheel to adjust to the unexpected irregularities of the route. Instead, the economy needs a way to prohibit the monetary passenger in the back seat from occasionally leaning over and giving the steering wheel a jerk that sends the car off the road. According to Friedman, the car will travel down the road just fine unless the Federal Reserve destabilizes it.

Lerner’s analogy implied an internally unstable economy that needs steering through discretionary government stabilization policy. Friedman’s modification of the analogy implied a generally stable economy that is destabilized by inappropriate monetary policy by the Federal Reserve. For Lerner, stability required active use of fiscal and monetary policy. For Friedman, macroeconomic stability required a monetary rule forcing the Federal Reserve to increase the money supply at a set, steady annual rate.*

*In his later years, Friedman softened his call for a monetary rule, acknowledging that the Fed had become much more skillful at keeping the rate of inflation in check through prudent monetary policy.

Monetarists argue that a monetary rule would tie increases in the money supply to the typical rightward shift of long-run aggregate supply. In view of the direct link between changes in the money supply and aggregate demand, this would ensure that the AD curve would shift rightward, as from AD_1 to AD_2 , each year. As a result, while GDP increases from Q_1 to Q_2 , the price level would remain constant at P_1 . A monetary rule, then, would promote steady growth of real output along with price stability.

FIGURE 39.3 Rationale for a monetary rule. A monetary rule that required the Fed to increase the money supply at an annual rate linked to the long-run increase in potential GDP would shift aggregate demand rightward, as from AD_1 to AD_2 , at the same pace as the shift in long-run aggregate supply, here, AS_{LR1} to AS_{LR2} . Thus the economy would experience growth without inflation or deflation.

Generally, rational expectations economists also support a monetary rule. They conclude that an expansionary or restrictive monetary policy would alter the rate of inflation but not real output. Suppose, for example, the Fed implements an easy money policy to reduce interest rates, expand investment spending, and boost real GDP. On the basis of past experience and economic knowledge, the public would anticipate that this policy is inflationary and would take protective actions. Workers would press for higher nominal wages; firms would raise their product prices; and lenders would lift their nominal interest rates on loans.

All these responses are designed to prevent inflation from having adverse effects on the real income of workers, businesses, and lenders. But collectively they would immediately raise wage and price levels. So the increase in aggregate demand brought about by the expansionary monetary policy would be completely dissipated in higher prices and wages. Real output and employment would not be increased by the easy money policy.

In this view, the combination of rational expectations and instantaneous market adjustments dooms discretionary monetary policy to ineffectiveness. If discretionary monetary policy produces only inflation (or deflation), say the RET economists, then it makes sense to limit the Fed's discretion and to require that Congress enact a monetary rule consistent with price stability at all times.

In recent decades, the call for a Friedman-type monetary rule has faded. In 2012, the Fed did, however, adopt a flexible version of another type of monetary rule. Under **inflation targeting**, the Fed commits to adjusting monetary policy as

necessary to achieve a publicly announced inflation rate. The Fed's choice for its **target rate of inflation** was 2 percent per year, in line with the target rates chosen around the same time by the European Central Bank, the Bank of England, and the Bank of Japan.

Strictly interpreted, inflation targeting would focus the Fed's attention nearly exclusively on controlling inflation and deflation, rather than on counteracting business fluctuations. Proponents of strict inflation targeting generally believe the economy will have fewer, shorter, and less severe business cycles if the Fed adheres to the rule "Set a known inflation goal and achieve it." The Fed, however, decided that its version of inflation targeting would be more flexible, with the Fed reserving the right to use monetary policy as necessary to smooth the business cycle even if doing so might cause inflation to deviate from the target rate of 2 percent.

We discussed another modern monetary rule—the Taylor rule—in Chapter 36. This rule specifies how the Fed should alter the federal funds rate under differing economic circumstances. Another monetary rule, nominal GDP targeting, is discussed in this chapter's Last Word.

Balanced Budget Monetarists and new classical economists question the effectiveness of fiscal policy. At the extreme, a few of them favor a constitutional amendment requiring that the federal government balance its budget annually. Others simply suggest that government be "passive" in its fiscal policy, not intentionally creating budget deficits or surpluses. They believe that deficits and surpluses caused by recession or inflationary expansion will eventually correct themselves as the economy self-corrects to its full-employment output.

Monetarists are particularly strong in their opposition to expansionary fiscal policy. They believe that the deficit spending accompanying such a policy has a strong tendency to "crowd out" private investment. Suppose government runs a budget deficit by printing and selling U.S. securities—that is, by borrowing from the public. By engaging in such borrowing, the government is competing with private businesses for funds. The borrowing increases the demand for money, which then raises the interest rate and crowds out a substantial amount of private investment that would otherwise have been profitable. The net effect of a budget deficit on aggregate demand therefore is unpredictable and, at best, modest.

RET economists reject discretionary fiscal policy for the same reason they reject active monetary policy: They don't think it works. Business and labor will immediately adjust their behavior in anticipation of the price-level effects of a change in fiscal policy. The economy will move directly to the anticipated new price level. Like monetary policy, say the RET theorists, fiscal policy can move the economy along its vertical long-run aggregate supply curve. But because its effects on inflation are fully anticipated, fiscal policy cannot alter real GDP even in the short run. The best course of action for government is to balance its budget.

In Defense of Discretionary Stabilization Policy

Mainstream economists oppose both a strict, Friedman-style monetary rule and a balanced-budget requirement. They believe that monetary policy and fiscal policy are important tools for achieving and maintaining full employment, price stability, and economic growth.

Discretionary Monetary Policy In supporting discretionary monetary policy, mainstream economists argue that the rationale for the Friedman monetary rule is flawed. While there is indeed a close relationship between the money supply and nominal GDP over long periods, in shorter periods this relationship breaks down. The reason is that the velocity of money has proved to be more variable and unpredictable than monetarists contend. Arguing that velocity is variable both cyclically and over time, mainstream economists contend that a constant annual rate of increase in the money supply might not eliminate fluctuations in aggregate demand. In terms of the equation of exchange, a steady rise of M does not guarantee a steady expansion of aggregate demand because V —the rate at which money is spent—can change.

Look again at Figure 39.3, in which we demonstrated the monetary rule: Expand the money supply annually by a fixed percentage, regardless of the state of the economy. During the period in question, optimistic business expectations might create a boom in investment spending and thus shift the aggregate demand curve to some location to the right of AD_2 . (You may want to pencil in a new AD curve, labeling it AD_3 .) The price level would then rise above P_1 ; that is, demand-pull inflation would occur. In this case, the monetary rule will not accomplish its goal of maintaining price stability. Mainstream economists say that the Fed can use a restrictive monetary policy to reduce the excessive investment spending and thereby hold the rightward shift of aggregate demand to AD_2 , thus avoiding inflation.

Similarly, suppose instead that investment declines because of pessimistic business expectations. Aggregate demand will then increase by some amount less than the increase from AD_1 to AD_2 in Figure 39.3. Again, the monetary rule fails the stability test: The price level sinks below P_1 (deflation occurs). Or if the price level is inflexible downward at P_1 , the economy will not achieve its full-employment output (unemployment rises). An expansionary monetary policy can help avoid each outcome.

Mainstream economists quip that the trouble with the monetary rule is that it tells the policymaker, “Don’t do something; just stand there.”

Discretionary Fiscal Policy Mainstream economists support the use of fiscal policy to keep recessions from deepening or to keep mild inflation from becoming severe inflation. They recognize the possibility of crowding out but do

not think it is a serious problem when business borrowing is depressed, as is usually the case in recession. Because politicians can abuse fiscal policy, most economists feel that it should be held in reserve for situations where monetary policy appears to be ineffective or working too slowly.

As indicated earlier, mainstream economists oppose requirements to balance the budget annually. Tax revenues fall sharply during recessions and rise briskly during periods of demand-pull inflation. Therefore, a law or a constitutional amendment mandating an annually balanced budget would require that the government increase tax rates and reduce government spending during recession and reduce tax rates and increase government spending during economic booms. The first set of actions would worsen recession, and the second set would fuel inflation.

Policy Successes

Finally, mainstream economists point out several specific policy successes in the past four decades:

- A tight money policy dropped inflation from 13.5 percent in 1980 to 3.2 percent in 1983.
- An expansionary fiscal policy reduced the unemployment rate from 9.7 percent in 1982 to 5.5 percent in 1988.
- An easy money policy helped the economy recover from the 1990–1991 recession.
- Judicious tightening of monetary policy in the mid-1990s, and then again in the late 1990s, helped the economy remain on a noninflationary, full-employment growth path.
- In late 2001 and 2002, expansionary fiscal and monetary policy helped the economy recover from a series of economic blows, including the collapse of numerous Internet start-up firms; a severe decline in investment spending; the impacts of the terrorist attacks of September 11, 2001; and a precipitous decline in stock values.
- In 2004 and 2005 the Fed tempered continued expansionary fiscal policy by increasing the federal funds rate in $\frac{1}{4}$ percentage-point increments from 1 percent to 4.25 percent. The economy expanded briskly in those years, while inflation stayed in check. The mild inflation was particularly impressive because the average price of a barrel of crude oil rose from \$24 in 2002 to \$55 in 2005. The Fed’s further increases in interest rates to 5.25 percent in 2006 also kept inflation mild that year and the next despite continued strong growth and oil reaching \$99 per barrel in late 2007.
- In 2007 the Fed vigorously responded to a crisis in the mortgage market by ensuring monetary liquidity in the banking system. Besides aggressively lowering the federal funds rate from 5.25 percent in the summer of

2007 to just 2 percent in April 2008, the Fed greatly increased the reserves of the banking system by creating and using its term auction facility. It also undertook other lender-of-last-resort actions to unfreeze credit and prevent a possible collapse of the entire financial system. During the severe recession of 2007–2009, the Fed lowered the federal funds rate further, holding it in the 0 to 0.25 percent range to break the downward slide of the economy and help promote economic recovery.

QUICK REVIEW 39.3

- ✓ Mainstream economists disagree with monetarist and rational expectations economists as to whether the Fed should use rules or utilize discretion.
- ✓ Monetarist and rational expectations economists oppose discretion because they believe that discretion adds more instability to the business cycle than it cures.
- ✓ Mainstream economists oppose strict monetary rules and defend both monetary and fiscal policy discretion because they believe that both theory and evidence suggest that discretionary policies are helpful in achieving full employment, price stability, and economic growth.

Summary of Alternative Views

L039.4 Summarize the fundamental ideas and policy implications of mainstream macroeconomics, monetarism, and rational expectations theory.

In Table 39.1, we summarize the fundamental ideas and policy implications of three macroeconomic theories: mainstream macroeconomics, monetarism, and rational expectations theory. Note that we have broadly defined new classical economics to include both monetarism and the rational expectations theory since both adhere to the view that the economy tends automatically to achieve equilibrium at its full-employment output.

These different perspectives have obliged mainstream economists to rethink some of their fundamental principles and to revise many of their positions. Although considerable disagreement remains, mainstream macroeconomists agree with monetarists that “money matters” and that excessive growth of the money supply is the major cause of long-lasting, rapid inflation. They also agree with RET proponents and theorists of coordination failures that expectations matter. If government can create expectations of price stability, full employment, and economic growth, households and firms will tend to act in ways to make them happen. In short, thanks to ongoing challenges to conventional wisdom, macroeconomics continues to evolve.

Market Monetarism

Market Monetarists Call for a New Monetary Rule That Would Institutionalize Fed Policy Responses to Changes in Real Output and Inflation.

In the aftermath of the Great Recession of 2007–2008, a new breed of “market monetarists” suggested that the Fed and other central banks should use prediction markets to adjust monetary policy.

In prediction markets, people can place bets on how likely it is that a particular political or financial outcome will end up happening. There are, for example, many commodities futures markets where people can bet on things like the price of corn next January or the price of oil in five years.

Extensive studies have shown that prediction markets make by far the most accurate predictions about the future—much better than those made by individual experts or even groups of experts attempting to pool their many decades of expertise. The superior prognosticating performance of prediction markets appears to be due to the fact that they incorporate the knowledge and insights of everyone who participates. As a result, even information that is only known to a few nonexperts can affect and improve the prediction.

Prediction markets are not perfect. They do make mistakes—for instance predicting the wrong candidate to win the presidential election or predicting that the price of oil will be \$46 per barrel in July whereas the actual price ends up being \$53 per barrel. But because prediction markets are the best available tool for predicting future outcomes, market monetarists want to piggyback on their predictive accuracy to help the Fed set monetary policy. In particular, they argue that the Fed should set up a prediction market for nominal GDP and then use the predictions generated by that market to adjust monetary policy.

As you know, nominal GDP can grow for two reasons: inflation or increases in real GDP. Market monetarists point out that if you look back over many decades of data, nominal GDP growth in the United States has averaged about 5 percent per year. Of that amount, about 3 percent per year has on average been due to real GDP growth while the remaining 2 percent has been caused by inflation.

What market monetarists want is for the Fed to use a nominal GDP prediction market to guide monetary policy. The Fed’s goal would be for the prediction market to always be predicting 5 percent growth in nominal GDP. If the prediction ever deviated from that 5 percent target, the Fed would loosen or tighten monetary policy in whatever way is needed for the prediction to adjust back to 5 percent.

To see how this monetary policy rule would work, suppose that the prediction market for nominal GDP is forecasting only 4 percent nominal GDP growth next year (rather than the desired rate of 5 percent). Because prediction markets make the most accurate forecasts, this 4 percent prediction will be our best available information on

Source: © Kulka/zefa/Corbis

what is likely to happen with the economy next year. And since what is likely to happen is less than the target rate of 5 percent, stimulus will be called for. Market monetarists would want the Fed to loosen monetary policy and stimulate the economy until the participants in the nominal GDP prediction market are “voting with their pocket-books” that nominal GDP will grow by 5 percent next year. When the predicted growth rate reaches 5 percent, the Fed can stop stimulating.

On the flip side, if the prediction market were forecasting 7 percent nominal GDP growth next year rather than the desired 5 percent, market monetarists would want the Fed to tighten monetary policy until the market’s prediction fell back down to the 5 percent target rate. That way, contractionary monetary policy would only be applied if and when the prediction market is indicating that the economy is overheating (relative to the 5 percent target growth rate for nominal GDP). Once the prediction market is indicating that the economy is on target again, contractionary actions can end and the Fed can switch to a neutral policy stance (i.e., neither expansionary nor contractionary).

Market monetarism has prompted a vigorous debate. Some opponents argue that “targeting the forecast” would overly constrain the Fed’s discretion when reacting to severe crises while others point out that a 5 percent target for nominal GDP growth would prevent real GDP growth from ever exceeding 5 percent per year. So while market monetarism has garnered several prominent proponents, including Nobel Laureate Paul Krugman and former Council of Economic Advisors Chairwoman Christina Romer, the debate over an optimal monetary policy rule will continue.

SUMMARY

L039.1 Describe alternative perspectives on the causes of macroeconomic instability, including the views of mainstream economists, monetarists, real-business-cycle advocates, and proponents of coordination failures.

The mainstream view is that macro instability is caused by a combination of price stickiness and shocks to aggregate demand or aggregate supply. With prices inflexible in the shorter run, changes in aggregate demand or short-run aggregate supply result in changes in output and employment. In the long run when both input and output prices are fully flexible, the economy will produce at potential output.

Monetarism focuses on the equation of exchange: $MV = PQ$. Because velocity is thought to be stable, changes in M create changes in nominal GDP ($= PQ$). Monetarists believe that the most significant cause of macroeconomic instability has been inappropriate monetary policy. Rapid increases in M cause inflation; insufficient growth of M causes recession. In this view, a major cause of the Great Depression was inappropriate monetary policy, which allowed the money supply to decline by roughly one-third.

Real-business-cycle theory views changes in resource availability and technology (real factors), which alter productivity, as the main causes of macroeconomic instability. In this theory, shifts of the economy's long-run aggregate supply curve change real output. In turn, money demand and money supply change, shifting the aggregate demand curve in the same direction as the initial change in long-run aggregate supply. Real output thus can change without a change in the price level.

A coordination failure is said to occur when people lack a way to coordinate their actions in order to achieve a mutually beneficial equilibrium. Depending on people's expectations, the economy can come to rest at either a good equilibrium (noninflationary full-employment output) or a bad equilibrium (less-than-full-employment output or demand-pull inflation). A bad equilibrium is a result of a coordination failure.

The rational expectations theory rests on two assumptions: (1) With sufficient information, people's beliefs about future economic outcomes accurately reflect the likelihood that those outcomes will occur; and (2) markets are highly competitive, and prices and wages are flexible both upward and downward.

L039.2 Discuss why new classical economists believe the economy will “self-correct” from aggregate demand and aggregate supply shocks.

New classical economists (monetarists and rational expectations theorists) see the economy as automatically correcting itself when disturbed from its full-employment level of real output. In RET, unanticipated changes in aggregate demand change the price level, and in the short run this leads firms to change output. But once the firms realize that all prices are changing (including nominal wages) as part of general inflation or deflation, they restore their output to the previous level. Anticipated changes in aggregate demand produce only changes in the price level, not changes in real output.

Mainstream economists reject the new classical view that all prices and wages are flexible downward. They contend that nominal

wages, in particular, are inflexible downward because of several factors, including labor contracts, efficiency wages, and insider-outsider relationships. This means that declines in aggregate demand lower real output, not only wages and prices.

L039.3 Identify and describe the variations of the debate over “rules” versus “discretion” in conducting stabilization policy.

Monetarist and rational expectations economists say the Fed should adhere to some form of policy rule, rather than rely exclusively on discretion. The Friedman rule would direct the Fed to increase the money supply at a fixed annual rate equal to the long-run growth of potential GDP. In 2012, the Fed took another path, however, and adopted an inflation target of 2 percent per year, thereby committing itself to adjusting monetary policy to reach that goal except in extreme cases where different rates of inflation might be necessary to smooth the business cycle. Monetarist and rational expectation economists also support maintaining a “neutral” fiscal policy, as opposed to using discretionary fiscal policy to create budget deficits or budget surpluses. A few monetarists and rational expectations economists favor a constitutional amendment requiring that the federal government balance its budget annually.

Mainstream economists oppose strict, Friedman-style monetary rules and a balanced-budget requirement, and defend discretionary monetary and fiscal policies. They say that both theory and evidence suggest that such policies are helpful in achieving full employment, price stability, and economic growth.

L039.4 Summarize the fundamental ideas and policy implications of mainstream macroeconomics, monetarism, and rational expectations theory.

Macroeconomics continues to evolve because of the debate among the three main schools of economic thought: the mainstream, monetarism, and rational expectations.

Mainstream economics believes the economy to be potentially unstable and prone to business cycles due to sticky prices and wages interacting with economic shocks. The mainstream believes in active monetary and fiscal policy that can change AD through the multiplier process and that changes in the money supply affect the economy by changing the interest rate and investment. The mainstream believes the velocity of money to be unstable and holds that cost-push inflation exists and is caused by AS shocks.

Monetarism believes the economy to be fundamentally stable unless inappropriate monetary policies are applied. It believes wages and prices are fully flexible at all time horizons, allowing the economy to adjust on its own back to equilibrium. It argues that business cycles will only occur if monetary policy is either overly tight or overly loose. To prevent either, monetarists support the application of a *monetary rule* to guide monetary policy. Monetarism views the velocity of money as stable and believes cost-push inflation to be impossible in the long run in the absence of excessive money supply growth. Monetarists believe that fiscal policy cannot affect AD or GDP unless there are accompanying changes in monetary policy. On the other hand, monetary policy can shift AD and thereby affect GDP.

The rational expectations camp believes the economy to be stable in the long run at the natural rate of unemployment due to its assumption that prices are flexible at all time horizons. But over shorter time horizons, recessions and booms can happen due to unexpected AD or AS shocks. Rational expectations proponents support a monetary rule in order to guide expectations, so that monetary policy changes will never be a surprise that could shift the economy

away from its equilibrium. They also agree with monetarists in the belief that cost-push inflation should be impossible without excessive money supply growth. Finally, rational expectations economists believe that anticipated fiscal and monetary policy changes will have no effect on GDP because they will lead only to price-level changes. For either to be effective in shifting GDP in the short run, they must come as a surprise.

REVIEW QUESTIONS

1. If prices are sticky and the number of dollars of gross investment unexpectedly increases, the _____ curve will shift _____. **LO39.1**
 - a. AD; right.
 - b. AD; left.
 - c. AS; right.
 - d. AS; left.
2. First, imagine that both input and output prices are fixed in the economy. What does the aggregate supply curve look like? If AD decreases in this situation, what will happen to equilibrium output and the price level? Next, imagine that input prices are fixed, but output prices are flexible. What does the aggregate supply curve look like? In this case, if AD decreases, what will happen to equilibrium output and the price level? Finally, if

both input and output prices are fully flexible, what does the aggregate supply curve look like? In this case, if AD decreases, what will happen to equilibrium output and the price level? (To check your answers, review Figures 32.3, 32.4, and 32.5 in Chapter 32). **L039.1**

3. Suppose that the money supply is \$1 trillion and money velocity is 4. Then the equation of exchange would predict nominal GDP to be: **L039.1**
 - a. \$1 trillion.
 - b. \$4 trillion.
 - c. \$5 trillion.
 - d. \$8 trillion.
4. If the money supply fell by 10 percent, a monetarist would expect nominal GDP to _____. **L039.1**
 - a. Rise.
 - b. Fall.
 - c. Stay the same.
5. An economy is producing at full employment when AD unexpectedly shifts to the left. A new classical economist would assume that as the economy adjusted back to producing at full employment, the price level would _____. **L039.2**
 - a. Increase.
 - b. Decrease.
 - c. Stay the same.
6. Use an AD-AS graph to demonstrate and explain the price-level and real-output outcome of an anticipated decline in aggregate demand, as viewed by RET economists. (Assume that the economy initially is operating at its full-employment level of output.) Then demonstrate and explain on the same graph the outcome as viewed by mainstream economists. **L039.2**
7. Place “MON,” “RET,” or “MAIN” beside the statements that most closely reflect monetarist, rational expectations, or mainstream views, respectively: **L039.4**
 - a. Anticipated changes in aggregate demand affect only the price level; they have no effect on real output.
 - b. Downward wage inflexibility means that declines in aggregate demand can cause long-lasting recession.
 - c. Changes in the money supply M increase PQ ; at first only Q rises, because nominal wages are fixed, but once workers adapt their expectations to new realities, P rises and Q returns to its former level.
 - d. Fiscal and monetary policies smooth out the business cycle.
 - e. The Fed should increase the money supply at a fixed annual rate.

PROBLEMS

1. Suppose that the money supply and the nominal GDP for a hypothetical economy are \$96 billion and \$336 billion, respectively. What is the velocity of money? How will households and businesses react if the central bank reduces the money supply by \$20 billion? By how much will nominal GDP have to fall to restore equilibrium, according to the monetarist perspective? **L039.1**
2. Assume the following information for a hypothetical economy in year 1: money supply = \$400 billion; long-term annual growth of potential GDP = 3 percent; velocity = 4. Assume

that the banking system initially has no excess reserves and that the reserve requirement is 10 percent. Also suppose that velocity is constant and that the economy initially is operating at its full-employment real output. **L039.1**

- a. What is the level of nominal GDP in year 1?
- b. Suppose the Fed adheres to a monetary rule through open-market operations. What amount of U.S. securities will it have to sell to, or buy from, banks or the public between years 1 and 2 to meet its monetary rule?

Moreover, they may have driven to the trailheads in Japanese-made Toyotas or German-made BMWs, sipping coffee from Brazil or snacking on bananas from Honduras.

International trade and the global economy affect all of us daily, whether we are hiking in the wilderness, driving our cars, buying groceries, or working at our jobs. We cannot “leave the world behind.” We are enmeshed in a global web of economic relationships, such as trading goods and services, multinational corporations, cooperative ventures among the world's firms, and ties among the world's financial markets.

The focus of this chapter is the trading of goods and services. Then in Chapter 41, we examine the U.S. balance of payments, exchange rates, and U.S. trade deficits. In Chapter 42, we look at the economics of developing nations.

*Note to Instructors: If you prefer to cover international trade early in your course, you can assign this chapter at the end of either Part 1 or Part 2. This chapter builds on the introductory ideas of opportunity costs, supply and demand analysis, and economic efficiency but does not require an understanding of either market failures or government failures.

Some Key Trade Facts

LO40.1 List and discuss several key facts about international trade.

The following are several important facts relating to international trade.

- U.S. exports and imports have more than doubled as percentages of GDP since 1980.
- A *trade deficit* occurs when imports exceed exports. The United States has a trade deficit in goods. In 2015, U.S. imports of goods exceeded U.S. exports of goods by \$529 billion.
- A *trade surplus* occurs when exports exceed imports. The United States has a trade surplus in services (such as air transportation services and financial services). In 2015, U.S. exports of services exceeded U.S. imports of services by \$220 billion.
- Principal U.S. exports include chemicals, agricultural products, consumer durables, semiconductors, and aircraft; principal imports include petroleum, automobiles, metals, household appliances, and computers.
- As with other advanced industrial nations, the United States imports many goods that are in some of the same categories as the goods that it exports. Examples: automobiles, computers, chemicals, semiconductors, and telecommunications equipment.
- Canada is the United States' most important trading partner quantitatively. In 2015, about 19 percent of U.S. exported goods were sold to Canadians, who in turn provided 13 percent of imported U.S. goods.
- The United States has a sizable trade deficit with China. In 2015 it was \$366 billion.
- Starting in 2012, the shale oil boom in the Plains States greatly reduced U.S. dependence on foreign oil, as can be seen in the statistics that keep track of trade between the United States and the members of OPEC. In 2011, before the boom, the United States imported \$191.5 billion of goods (mainly oil) from OPEC while exporting \$64.8 billion of goods to those countries. By 2015, U.S. imports had fallen to just \$66.2 billion while exports had risen to \$72.8 billion. The United States' oil usage had fallen so much that the United States ran its first-ever trade surplus with OPEC in 2015.
- The United States leads the world in the combined volume of exports and imports, as measured in dollars. China, the United States, Germany, Japan, and the Netherlands were the top five exporters by dollar in 2015.

GLOBAL PERSPECTIVE 40.1

Shares of World Exports, Selected Nations

China has the largest share of world exports, followed by Germany and the United States. The eight largest export nations account for about 44.8 percent of world exports.

Source: *International Trade Statistics, 2015*, WTO Publications.

- Currently, the United States provides about 8.5 percent of the world's exports. (See Global Perspective 40.1.)
- Exports of goods and services (on a national income account basis) make up about 13 percent of total U.S. output. That percentage is much lower than the percentage in many other nations, including Belgium, the Netherlands, Germany, Canada, and the United Kingdom. (See Global Perspective 40.2.)
- China has become a major international trader, with an estimated \$2.2 trillion of exports in 2015. Other Asian economies—including South Korea, Taiwan, and Singapore—are also active in international trade. Their combined exports exceed those of France, Britain, or Italy.
- International trade links world economies. Through trade, changes in economic conditions in one place on the globe can quickly affect other places.
- International trade is often at the center of debates over economic policy, both within the United States and internationally.

With this information in mind, let's turn to the economics of international trade.

The Economic Basis for Trade

LO40.2 Define comparative advantage and demonstrate how specialization and trade add to a nation's output.

Sovereign nations, like individuals and the regions of a nation, can gain by specializing in the products they can produce with the greatest relative efficiency and by trading for the goods they cannot produce as efficiently. The simple answer to the question “Why do nations trade?” is “They trade because it is beneficial.” The benefits that emerge relate to three underlying facts:

- The distribution of natural, human, and capital resources among nations is uneven; nations differ in their endowments of economic resources.
- Efficient production of various goods requires different technologies, and not all nations have the same level of technological expertise.
- Products are differentiated as to quality and other attributes, and some people may prefer certain goods imported from abroad rather than similar goods produced domestically.

To recognize the character and interaction of these three facts, think of China, which has abundant and inexpensive labor. As a result, China can produce efficiently (at low cost

of other goods forgone) a variety of **labor-intensive goods**, such as textiles, electronics, apparel, toys, and sporting goods.

In contrast, Australia has vast amounts of land and can inexpensively produce such **land-intensive goods** as beef, wool, and meat. Mexico has the soil, tropical climate, rainfall, and ready supply of unskilled labor that allow for the efficient, low-cost production of vegetables. Industrially advanced economies such as the United States and Germany that have relatively large amounts of capital can inexpensively produce goods whose production requires much capital, including such **capital-intensive goods** as airplanes, automobiles, agricultural equipment, machinery, and chemicals.

Also, regardless of their resource intensities, nations can develop individual products that are in demand worldwide because of their special qualities. Examples: fashions from Italy, chocolates from Belgium, software from the United States, and watches from Switzerland.

The distribution of resources, technology, and product distinctiveness among nations is relatively stable in short time periods but certainly can change over time. When that distribution changes, the relative efficiency and success that nations have in producing and selling goods also change. For example, in the past several decades, South Korea has greatly expanded its stock of capital. Although South Korea was primarily an exporter of agricultural products and raw materials a half-century ago, it now exports large quantities of manufactured goods. Similarly, the new technologies that gave us synthetic fibers and synthetic rubber drastically altered the resource mix needed to produce fibers and rubber and changed the relative efficiency of nations in manufacturing them.

As national economies evolve, the size and quality of their labor forces may change, the volume and composition of their capital stocks may shift, new technologies may develop, and even the quality of land and the quantity of natural resources may be altered. As such changes take place, the relative efficiency with which a nation can produce specific goods will also change. As economists would say, comparative advantage can and does sometimes change.

Comparative Advantage

In an open economy (one with an international sector), a country produces more of certain goods (exports) and fewer of other goods (imports) than it would otherwise. Thus, the country shifts the use of labor and other productive resources toward export industries and away from import industries. For example, in the presence of international trade, the United States uses more resources to make commercial aircraft and to grow wheat and fewer resources to make television sets and sew clothes. So we ask: Do such shifts of resources make economic sense? Do they enhance U.S. total output and thus the U.S. standard of living?

A CPA and a House Painter

Suppose that Madison, a certified public accountant (CPA), is a swifter painter than Mason, the professional painter she is thinking of hiring. Also assume that Madison can earn \$50 per hour as an accountant but would have to pay Mason \$15 per hour.

And suppose that Madison would need 30 hours to paint her house but Mason would need 40 hours.

Should Madison take time from her accounting to paint her own house, or should she hire the painter? Madison's opportunity cost of painting her house is \$1,500 (= 30 hours of sacrificed CPA time \times \$50 per CPA hour). The cost of hiring Mason is only \$600 (= 40 hours of painting \times \$15 per hour of painting). Although Madison is better at both accounting and painting, she will get her house painted at lower cost by specializing in accounting and using some of her earnings from accounting to hire a house painter.

Similarly, Mason can reduce his cost of obtaining accounting services by specializing in painting and using some of his income to hire Madison to prepare his income tax forms. Suppose Mason would need 10 hours to prepare his tax return, while Madison could handle the task in 2 hours. Mason would sacrifice \$150 of income (= 10 hours of painting time \times \$15 per hour) to do something he could hire Madison to do for \$100 (= 2 hours of CPA time \times \$50 per CPA hour). By specializing in painting and hiring Madison to prepare his tax return, Mason lowers the cost of getting his tax return prepared.

We will see that what is true for our CPA and house painter is also true for nations. Specializing on the basis of comparative advantage enables nations to reduce the cost of obtaining the goods and services they desire.

The answers are affirmative. Specialization and international trade increase the productivity of U.S. resources and allow the United States to obtain greater total output than otherwise would be possible. These benefits are the result of exploiting both *absolute advantages* and *comparative advantages*. A country is said to have an *absolute advantage* over other producers of a product if it is the most efficient producer of that product (by which we mean that it can produce more output of that product from any given amount of resource inputs than can any other producer). A country is said to have a *comparative advantage* over other producers of a product if it can produce the product at a lower opportunity

cost (by which we mean that it must forgo less output of alternative products when allocating productive resources to producing the product in question).

In 1776, Adam Smith used the concept of absolute advantage to argue for international specialization and trade. His point was that nations would be better off if each specialized in the production of those products in which it had an absolute advantage and was therefore the most efficient producer:

It is the maxim of every prudent master of a family, never to attempt to make at home what it will cost him more to make than to buy. The taylor does not attempt to make his own shoes, but buys them of the shoemaker. The shoemaker does not attempt to make his own clothes, but employs a taylor. The farmer attempts to make neither the one nor the other, but employs those different artificers. . . .

What is prudence in the conduct of every private family, can scarce be folly in that of a great kingdom. If a foreign country can supply us with a commodity cheaper than we can make it, better buy it of them with some part of the produce of our own industry, employed in a way in which we have some advantage.¹

In the early 1800s, David Ricardo extended Smith's idea by demonstrating that it is advantageous for a country to specialize and trade with another country even if it is more productive in all economic activities than that other country. Stated more formally, a nation does not need Smith's absolute advantage—total superiority in the efficiency with which it produces products—to benefit from specialization and trade. It needs only a comparative advantage.

The nearby Consider This box (A CPA and a House Painter) provides a simple, two-person illustration of Ricardo's principle of comparative advantage. Be sure to read it now because it will greatly help you understand the graphical analysis that follows.

QUICK REVIEW 40.1

- ✓ International trade enables nations to specialize, increase productivity, and increase the amount of output available for consumption.
- ✓ A country is said to have an *absolute advantage* over the other producers of a product if it can produce the product more efficiently, by which we mean that it can produce more of the product from any given amount of resource inputs than can any other producer.
- ✓ A country is said to have a *comparative advantage* over the other producers of a product if it can produce the product at a lower opportunity cost, by which we mean that it must forgo less of the output of alternative products when allocating resources to producing the product in question.

¹Adam Smith, *The Wealth of Nations* (originally published, 1776; New York: Modern Library, 1937), p. 424.

Two Isolated Nations

Our goal is to place the idea of comparative advantage into the context of trading nations. Our method is to build a simple model that relies on the familiar concepts of production possibilities curves. Suppose the world consists of just two nations, the United States and Mexico. Also for simplicity, suppose that the labor forces in the United States and Mexico are of equal size. Each nation can produce both beef and raw (unprocessed) vegetables but at different levels of economic efficiency. Suppose the U.S. and Mexican domestic production possibilities curves for beef and vegetables are those shown in Figure 40.1a and Figure 40.1b. Note three realities relating to the production possibilities curves in the two graphs:

- **Constant costs** The curves derive from the data in Table 40.1 and are drawn as straight lines, in contrast to the bowed-outward production possibilities frontiers we examined in Chapter 1. This means that we have replaced the law of increasing opportunity costs with the assumption of constant costs. This substitution simplifies our discussion but does not impair the validity of our analysis and conclusions. Later we will consider the effects of increasing opportunity costs.
- **Different costs** The production possibilities curves of the United States and Mexico reflect different resource mixes and differing levels of technology. Specifically, the differing slopes of the two curves reflect the numbers in the figures and reveal that the opportunity costs of producing beef and vegetables differ between the two nations.
- **U.S. absolute advantage in both** A producer (an individual, firm, or country) has an *absolute advantage*

over another producer if it can produce more of a product than the other producer using the same amount of resources. Because of our convenient assumption that the U.S. and Mexican labor forces are the same size, the two production possibilities curves show that the United States has an absolute advantage in producing both products. If the United States and Mexico use their entire (equal-size) labor forces to produce either vegetables or beef, the United States can produce more of either than Mexico. The United States, using the same number of workers as Mexico, has greater production possibilities. So output per worker—labor productivity—in the United States exceeds that in Mexico in producing both products.

Opportunity-Cost Ratio in the United States In Figure 40.1a, with full employment, the United States will operate at some point on its production possibilities curve. On that curve, it can increase its output of beef from 0 tons to 30 tons by forgoing 30 tons of vegetables output. So the slope of the production possibilities curve is 1 ($= 30 \text{ vegetables} / 30 \text{ beef}$), meaning that 1 ton of vegetables must be sacrificed for each extra ton of beef. In the United States the **opportunity-cost ratio** (domestic exchange ratio) for the two products is 1 ton of vegetables (V) for 1 ton of beef (B), or

United States: $1V \equiv 1B$ (The “ \equiv ” sign simply means “equivalent to.”)

Within its borders, the United States can “exchange” a ton of vegetables from itself for a ton of beef from itself. Our constant-cost assumption means that this exchange or opportunity-cost relationship prevails for all possible moves from one point to another along the U.S. production possibilities curve.

FIGURE 40.1 Production possibilities for the United States and Mexico. The two production possibilities curves show the combinations of vegetables and beef that the United States and Mexico can produce domestically. The curves for both countries are straight lines because we are assuming constant opportunity costs. (a) As reflected by the slope of $V\bar{B}$ in the left graph, the opportunity-cost ratio in the United States is 1 vegetable \equiv 1 beef. (b) The production possibilities curve $v\bar{b}$ in the right graph has a steeper slope, reflecting the different opportunity-cost ratio in Mexico of 2 vegetables \equiv 1 beef. The difference in the opportunity-cost ratios between the two countries defines their comparative advantages and is the basis for specialization and international trade.

TABLE 40.1 International Specialization According to Comparative Advantage and the Gains from Trade

Country	(1) Outputs before Specialization	(2) Outputs after Specialization	(3) Amounts Exported (–) and Imported (+)	(4) Outputs Available after Trade	(5) Gains from Specialization and Trade (4) – (1)
United States	18 beef	30 beef	–10 beef	20 beef	2 beef
	12 vegetables	0 vegetables	+15 vegetables	15 vegetables	3 vegetables
Mexico	8 beef	0 beef	+10 beef	10 beef	2 beef
	4 vegetables	20 vegetables	–15 vegetables	5 vegetables	1 vegetables

Opportunity-Cost Ratio in Mexico Mexico’s production possibilities curve in Figure 40.1b represents a different full-employment opportunity-cost ratio. In Mexico, 20 tons of vegetables must be given up to obtain 10 tons of beef. The slope of the production possibilities curve is 2 (= 20 vegetables/10 beef). This means that in Mexico the opportunity-cost ratio for the two goods is 2 tons of vegetables for 1 ton of beef, or

$$\text{Mexico: } 2V \equiv 1B$$

Self-Sufficiency Output Mix If the United States and Mexico are isolated and self-sufficient, then each country must choose some output mix on its production possibilities curve. It will select the mix that provides the greatest total utility or satisfaction. Let’s assume that combination point *A* in Figure 40.1a is the optimal mix in the United States. That is, society deems the combination of 18 tons of beef and 12 tons of vegetables preferable to any other combination of the goods available along the production possibilities curve. Suppose Mexico’s optimal product mix is 8 tons of beef and 4 tons of vegetables, indicated by point *Z* in Figure 40.1b. These choices by the two countries are reflected in column 1 of Table 40.1.

Specializing Based on Comparative Advantage

A producer (an individual, firm, or nation) has a **comparative advantage** in producing a particular product if it can produce that product at a lower opportunity cost than other producers. Comparative advantage is the key determinant in whether or not nations can gain from specialization and trade. In fact, absolute advantage turns out to be irrelevant.

In our example, for instance, the United States has an absolute advantage over Mexico in producing both vegetables and beef. But it is still the case that the United States can gain from specialization and trade with Mexico. That is because what actually matters is whether the opportunity costs of producing the two products (beef and vegetables) differ in the two countries. If they do, then each nation will enjoy a

comparative advantage in one of the products, meaning that it can produce that product at a lower opportunity cost than the other country. As a result, total output can increase if each country specializes in the production of the good in which it has the lower opportunity cost.

This idea is summarized in the **principle of comparative advantage**, which says that total output will be greatest when each good is produced by the nation that has the lowest domestic opportunity cost for producing that good. In our two-nation illustration, the United States has the lower domestic opportunity cost for beef; the United States must forgo only 1 ton of vegetables to produce 1 ton of beef, whereas Mexico must forgo 2 tons of vegetables for 1 ton of beef. The United States has a comparative (cost) advantage in beef and should specialize in beef production. The “world” (that is, the United States and Mexico) in our example would clearly not be economizing in the use of its resources if a high-cost producer (Mexico) produced a specific product (beef) when a low-cost producer (the United States) could have produced it. Having Mexico produce beef would mean that the world economy would have to give up more vegetables than is necessary to obtain a ton of beef.

Mexico has the lower domestic opportunity cost for vegetables. It must sacrifice only $\frac{1}{2}$ ton of beef to produce 1 ton of vegetables, while the United States must forgo 1 ton of beef to produce 1 ton of vegetables. Mexico has a comparative advantage in vegetables and should specialize in vegetable production. Again, the world would not be employing its resources economically if vegetables were produced by a high-cost producer (the United States) rather than by a low-cost producer (Mexico). If the United States produced vegetables, the world would be giving up more beef than necessary to obtain each ton of vegetables. Economizing requires that any particular good be produced by the nation having the lowest domestic opportunity cost or the nation having the comparative advantage for that good. The United States should produce beef, and Mexico should produce vegetables. The situation is summarized in Table 40.2.

A comparison of columns 1 and 2 in Table 40.1 verifies that specialized production enables the world to obtain more

TABLE 40.2 Comparative-Advantage Example: A Summary

Beef	Vegetables
Mexico: Must give up 2 tons of vegetables to get 1 ton of beef.	Mexico: Must give up $\frac{1}{2}$ ton of beef to get 1 ton of vegetables.
United States: Must give up 1 ton of vegetables to get 1 ton of beef.	United States: Must give up 1 ton of beef to get 1 ton of vegetables.

output from its fixed amount of resources. By specializing completely in beef, the United States can produce 30 tons of beef and no vegetables. Mexico, by specializing completely in vegetables, can produce 20 tons of vegetables and no beef. These figures exceed the yields generated without specialization: 26 tons of beef (= 18 in the United States + 8 in Mexico) and 16 tons of vegetables (= 12 in the United States + 4 in Mexico). As a result, the world ends up with 4 more tons of beef (= 30 tons – 26 tons) and 4 more tons of vegetables (= 20 tons – 16 tons) than it would if there were self-sufficiency and unspecialized production.

Terms of Trade

We have just seen that specialization in production will allow for the largest possible amounts of both beef and vegetables to be produced. But with each country specializing in the production of only one item, how will the vegetables that are all produced by Mexico and the beef that is all produced by the United States be divided between consumers in the two countries? The key turns out to be the **terms of trade**, the exchange ratio at which the United States and Mexico trade beef and vegetables.

Crucially, the terms of trade also establish whether each country will find it in its own better interest to bother specializing at all. This is because the terms of trade determine whether each country can “get a better deal” by specializing and trading than it could if it opted instead for self-sufficiency. To see how this works, note that because $1B \equiv 1V$ (= $1V \equiv 1B$) in the United States, it must get more than 1 ton of vegetables for each 1 ton of beef exported; otherwise, it will not benefit from exporting beef in exchange for Mexican vegetables. The United States must get a better “price” (more vegetables) for its beef through international trade than it can get domestically; otherwise, no gain from trade exists and such trade will not occur.

Similarly, because $1B \equiv 2V$ (= $2V \equiv 1B$) in Mexico, Mexico must obtain 1 ton of beef by exporting less than 2 tons of vegetables to get it. Mexico must be able to pay a lower “price” for beef in the world market than it must pay domestically, or else it will not want to trade. The international

exchange ratio or terms of trade must therefore lie somewhere between

$$1B \equiv 1V \text{ (United States' cost conditions)}$$

and

$$1B \equiv 2V \text{ (Mexico's cost conditions)}$$

Where between these limits will the world exchange ratio fall? The United States will prefer a rate close to $1B \equiv 2V$, say, $1B \equiv 1\frac{3}{4}V$. The United States wants to obtain as many vegetables as possible for each 1 ton of beef it exports. By contrast, Mexico wants a rate near $1B \equiv 1V$, say, $1B \equiv 1\frac{1}{4}V$. This is true because Mexico wants to export as few vegetables as possible for each 1 ton of beef it receives in exchange.

The actual exchange ratio depends on world supply and demand for the two products. If overall world demand for vegetables is weak relative to its supply and if the demand for beef is strong relative to its supply, the price of vegetables will be lower and the price of beef will be higher. The exchange ratio will settle nearer the $1B \equiv 2V$ figure the United States prefers. If overall world demand for vegetables is great relative to its supply and if the demand for beef is weak relative to its supply, the ratio will settle nearer the $1B \equiv 1V$ level favorable to Mexico. In this manner, the actual exchange ratio that is set by world supply and demand determines how the gains from international specialization and trade are divided between the two nations and, consequently, how the beef that is all produced in the United States and the vegetables that are all produced in Mexico get divided among consumers in the two countries. (We discuss equilibrium world prices later in this chapter.)

Gains from Trade

Suppose the international terms of trade are $1B \equiv 1\frac{1}{2}V$. The possibility of trading on these terms permits each nation to supplant its domestic production possibilities curve with a trading possibilities line (or curve), as shown in **Figure 40.2 (Key Graph)**. Just as a production possibilities curve shows the amounts of these products that a full-employment economy can obtain by shifting resources from one to the other, a **trading possibilities line** shows the amounts of the two products that a nation can obtain by specializing in one product and trading for the other. The trading possibilities lines in Figure 40.2 reflect the assumption that both nations specialize on the basis of comparative advantage: The United States specializes completely in beef (at point *B* in Figure 40.2a), and Mexico specializes completely in vegetables (at point *v* in Figure 40.2b).

Improved Alternatives With specialization and trade, the United States is no longer constrained by its domestic production possibilities line, which requires it to give up 1 ton of

FIGURE 40.2 Trading possibilities lines and the gains from trade. As a result of specialization and trade, both the United States and Mexico can have higher levels of output than the levels attainable on their domestic production possibilities curves. (a) The United States can move from point A on its domestic production possibilities curve to, say, A' on its trading possibilities line. (b) Mexico can move from Z to Z'.

QUICK QUIZ FOR FIGURE 40.2

- The production possibilities curves in graphs (a) and (b) imply:
 - increasing domestic opportunity costs.
 - decreasing domestic opportunity costs.
 - constant domestic opportunity costs.
 - first decreasing, then increasing domestic opportunity costs.
- Before specialization, the domestic opportunity cost of producing 1 unit of beef is:
 - 1 unit of vegetables in both the United States and Mexico.
 - 1 unit of vegetables in the United States and 2 units of vegetables in Mexico.
 - 2 units of vegetables in the United States and 1 unit of vegetables in Mexico.
 - 1 unit of vegetables in the United States and $\frac{1}{2}$ unit of vegetables in Mexico.
- After specialization and international trade, the world output of beef and vegetables is:
 - 20 tons of beef and 20 tons of vegetables.
 - 45 tons of beef and 15 tons of vegetables.
 - 30 tons of beef and 20 tons of vegetables.
 - 10 tons of beef and 30 tons of vegetables.
- After specialization and international trade:
 - the United States can obtain units of vegetables at less cost than it could before trade.
 - Mexico can obtain more than 20 tons of vegetables, if it so chooses.
 - the United States no longer has a comparative advantage in producing beef.
 - Mexico can benefit by prohibiting vegetables imports from the United States.

Answers: 1. c; 2. b; 3. c; 4. a

beef for every 1 ton of vegetables it wants as it moves up its domestic production possibilities line from, say, point B. Instead, the United States, through trade with Mexico, can get $1\frac{1}{2}$ tons of vegetables for every ton of beef that it exports to Mexico, as long as Mexico has vegetables to export. Trading possibilities line BV' thus represents the $1B \equiv 1\frac{1}{2}V$ trading ratio.

Similarly, Mexico, starting at, say, point v, no longer has to move down its domestic production possibilities curve,

giving up 2 tons of vegetables for each ton of beef it wants. It can now export just $1\frac{1}{2}$ tons of vegetables for each 1 ton of beef that it wants by moving down its trading possibilities line vb' .

Specialization and trade create a new exchange ratio between beef and vegetables, and that ratio is reflected in each nation's trading possibilities line. For both nations, this exchange ratio is superior to the unspecialized exchange ratio embodied in their respective production possibilities curves.

By specializing in beef and trading for Mexico's vegetables, the United States can obtain more than 1 ton of vegetables for 1 ton of beef. By specializing in vegetables and trading for U.S. beef, Mexico can obtain 1 ton of beef for less than 2 tons of vegetables. In both cases, self-sufficiency is inefficient and therefore undesirable.

Greater Output By specializing on the basis of comparative advantage and by trading for goods that are produced in the nation with greater domestic efficiency, the United States and Mexico can achieve combinations of beef and vegetables beyond their own individual production possibilities curves. Specialization according to comparative advantage results in a more efficient allocation of world resources, and larger outputs of both products are therefore available to both nations.

Suppose that at the $1B \equiv 1\frac{1}{2}V$ terms of trade, the United States exports 10 tons of beef to Mexico and, in return, Mexico exports 15 tons of vegetables to the United States. How do the new quantities of beef and vegetables available to the two nations compare with the optimal product mixes that existed before specialization and trade? Point *A* in Figure 40.2a reminds us that the United States chose 18 tons of beef and 12 tons of vegetables originally. But by producing 30 tons of beef and no vegetables and by trading 10 tons of beef for 15 tons of vegetables, the United States can obtain 20 tons of beef and 15 tons of vegetables. This new, superior combination of beef and vegetables is indicated by point *A'* in Figure 40.2a. Compared with the no-trade amounts of 18 tons of beef and 12 tons of vegetables, the United States' **gains from trade** are 2 tons of beef and 3 tons of vegetables.

Similarly, recall that Mexico's optimal product mix was 4 tons of vegetables and 8 tons of beef (point *Z*) before specialization and trade. Now, after specializing in vegetables and trading for beef, Mexico can have 5 tons of vegetables and 10 tons of beef. It accomplishes that by producing 20 tons of vegetables and no beef and exporting 15 tons of its vegetables in exchange for 10 tons of American beef. This new position is indicated by point *Z'* in Figure 40.2b. Mexico's gains from trade are 1 ton of vegetables and 2 tons of beef.

Points *A'* and *Z'* in Figure 40.2 are superior economic positions to points *A* and *Z*. This fact is enormously important! We know that a nation can expand its production possibilities boundary by (1) expanding the quantity and improving the quality of its resources or (2) realizing technological progress. We have now established that international trade can enable a nation to circumvent the output constraint illustrated by its production possibilities curve. An economy can grow by expanding international trade. The outcome of international specialization and trade is equivalent to having more and better resources or discovering and implementing improved production techniques.

Table 40.1 summarizes the transactions and outcomes in our analysis. Please give it one final careful review.

QUICK REVIEW 40.2

- ✓ The principle of comparative advantage says that total world output will be greatest when each good is produced by the nation that has the lowest domestic opportunity cost.
- ✓ The rate at which countries can trade units of one product for units of another product is referred to as the terms of trade.
- ✓ A trading possibilities line shows the amounts of two products that a nation can obtain by specializing in the production of one product and then trading for the other.

Misunderstanding the Gains from Trade

It is a common myth that the greatest benefit to be derived from international trade is greater domestic employment in the export sector. This suggests

that exports are “good” because they increase domestic employment, whereas imports are “bad” because they deprive people of jobs at home. As we have demonstrated, the true benefit created by international trade is the overall increase in output available through specialization and exchange.

A nation does not need international trade to operate *on* its production possibilities curve. It can fully employ its resources, including labor, with or without international trade. International trade, however, enables a country to reach a point of consumption beyond its domestic production possibilities curve. The gain from trade to a nation is the extra output obtained from abroad—the imports obtained for less sacrifice of other goods than if they were produced at home.

Trade with Increasing Costs

To explain the basic principles underlying international trade, we simplified our analysis in several ways. For example, we limited discussion to two products and two nations. But multiproduct and multinational analysis yield the same conclusions. We also assumed constant opportunity costs (linear production possibilities curves), which is a more substantive simplification. Let's consider the effect of allowing increasing opportunity costs (concave-to-the-origin production possibilities curves) to enter the picture.

Suppose that the United States and Mexico initially are at positions on their concave production possibilities curves where their domestic cost ratios are $1B \equiv 1V$ and $1B \equiv 2V$, as they were in our constant-cost analysis. As before, comparative advantage indicates that the United States should specialize in beef and Mexico in vegetables. But now, as the United States begins to expand beef production, its cost of beef will rise; it will have to sacrifice more than 1 ton of vegetables to get 1 additional ton of beef. Resources are no longer perfectly substitutable between alternative uses, as the constant-cost assumption implied. Resources less and less suitable to beef production must be allocated to the U.S. beef industry in expanding beef output, and that means increasing costs—the sacrifice of larger and larger amounts of vegetables for each additional ton of beef.

Similarly, suppose that Mexico expands vegetable production starting from its $1B \equiv 2V$ cost ratio position. As production increases, it will find that its $1B \equiv 2V$ cost ratio begins to rise. Sacrificing 1 ton of beef will free resources that are capable of producing only something less than 2 tons of vegetables because those transferred resources are less suitable to vegetable production.

As the U.S. cost ratio falls from $1B \equiv 1V$ and the Mexican ratio rises from $1B \equiv 2V$, a point will be reached where the cost ratios are equal in the two nations, perhaps at $1B \equiv 1\frac{3}{4}V$. At this point, the underlying basis for further specialization and trade—differing cost ratios—has disappeared, and further specialization is therefore uneconomical. And, most important, this point of equal cost ratios may be reached while the United States is still producing some vegetables along with its beef and Mexico is producing some beef along with its vegetables. The primary effect of increasing opportunity costs is less-than-complete specialization. For this reason, we often find domestically produced products competing directly against identical or similar imported products within a particular economy.

The Case for Free Trade

The case for free trade reduces to one compelling argument: Through free trade based on the principle of comparative advantage, the world economy can achieve a more efficient allocation of resources and a higher level of material well-being than it can without free trade.

Since the resource mixes and technological knowledge of the world's nations are all somewhat different, each nation can produce particular commodities at different real costs. Each nation should produce goods for which its domestic opportunity costs are lower than the domestic opportunity costs of other nations and exchange those goods for products for which its domestic opportunity costs are high relative to those of other nations. If each nation does this, the world will realize the advantages of geographic and human specialization. The

world and each free-trading nation can obtain a larger real income from the fixed supplies of resources available to it.

Government trade barriers lessen or eliminate gains from specialization. If nations cannot trade freely, they must shift resources from efficient (low-cost) to inefficient (high-cost) uses to satisfy their diverse wants. A recent study suggests that the elimination of trade barriers since the Second World War has increased the income of the average U.S. household by at least \$7,000 and perhaps by as much as \$13,000. These income gains are recurring; they happen year after year.²

One side benefit of free trade is that it promotes competition and deters monopoly. The increased competition from foreign firms forces domestic firms to find and use the lowest-cost production techniques. It also compels them to be innovative with respect to both product quality and production methods, thereby contributing to economic growth. And free trade gives consumers a wider range of product choices. The reasons to favor free trade are the same as the reasons to endorse competition.

A second side benefit of free trade is that it links national interests and breaks down national animosities. Confronted with political disagreements, trading partners tend to negotiate rather than make war.

QUICK REVIEW 40.3

- ✓ International trade enables nations to specialize, increase productivity, and increase output available for consumption.
- ✓ Comparative advantage means total world output will be greatest when each good is produced by the nation that has the lowest domestic opportunity cost.
- ✓ Specialization is less than complete among nations because opportunity costs normally rise as any specific nation produces more of a particular good.

Supply and Demand Analysis of Exports and Imports

L040.3 Describe how differences between world prices and domestic prices prompt exports and imports.

Supply and demand analysis reveals how equilibrium prices and quantities of exports and imports are determined. The amount of a good or a service a nation will export or import depends on differences between the equilibrium world price and the equilibrium domestic price. The interaction of *world* supply and demand determines the equilibrium **world price**—the price that equates the quantities supplied and

²Scott C. Bradford, Paul L. E. Grieco, and Gary C. Hufbauer, "The Payoff to America from Globalization," *The World Economy*, July 2006, pp. 893–916.

demanded globally. *Domestic supply* and demand determine the equilibrium **domestic price**—the price that would prevail in a closed economy that does not engage in international trade. The domestic price equates quantity supplied and quantity demanded domestically.

In the absence of trade, the domestic prices in a closed economy may or may not equal the world equilibrium prices. When economies are opened for international trade, differences between world and domestic prices encourage exports or imports. To see how, consider the international effects of such price differences in a simple two-nation world, consisting of the United States and Canada, that are both producing aluminum. We assume there are no trade barriers, such as tariffs and quotas, and no international transportation costs.

Supply and Demand in the United States

Figure 40.3a shows the domestic supply curve S_d and the domestic demand curve D_d for aluminum in the United States, which for now is a closed economy. The intersection of S_d and D_d determines the equilibrium domestic price of \$1 per pound and the equilibrium domestic quantity of 100 million pounds. Domestic suppliers produce 100 million pounds and sell them all at \$1 a pound. So there are no domestic surpluses or shortages of aluminum.

But what if the U.S. economy were opened to trade and the world price of aluminum were above or below this \$1 domestic price?

U.S. Export Supply If the aluminum price in the rest of the world (that is, Canada) exceeds \$1, U.S. firms will produce more than 100 million pounds and will export the excess domestic output. First, consider a world price of \$1.25. We see from the supply curve S_d that U.S. aluminum firms will produce 125 million pounds of aluminum at that price. The demand curve D_d tells us that the United States will purchase only 75 million pounds at \$1.25. The outcome is a domestic surplus of 50 million pounds of aluminum. U.S. producers will export those 50 million pounds at the \$1.25 world price.

What if the world price were \$1.50? The supply curve shows that U.S. firms will produce 150 million pounds of aluminum, while the demand curve tells us that U.S. consumers will buy only 50 million pounds. So U.S. producers will export the domestic surplus of 100 million pounds.

Toward the top of Figure 40.3b we plot the domestic surpluses—the U.S. exports—that occur at world prices above the \$1 domestic equilibrium price. When the world and domestic prices are equal (= \$1), the quantity of exports supplied is zero (point *a*). There is no surplus of domestic output

FIGURE 40.3 U.S. export supply and import demand. (a) Domestic supply S_d and demand D_d set the domestic equilibrium price of aluminum at \$1 per pound. At world prices above \$1, there are domestic surpluses of aluminum. At prices below \$1, there are domestic shortages. (b) Surpluses are exported (top curve), and shortages are met by importing aluminum (lower curve). The export supply curve shows the direct relationship between world prices and U.S. exports; the import demand curve portrays the inverse relationship between world prices and U.S. imports.

to export. But when the world price is \$1.25, U.S. firms export 50 million pounds of surplus aluminum (point *b*). At a \$1.50 world price, the domestic surplus of 100 million pounds is exported (point *c*).

The U.S. **export supply curve**, found by connecting points *a*, *b*, and *c*, shows the amount of aluminum U.S. producers will export at each world price above \$1. This curve *slopes upward*, indicating a direct or positive relationship between the world price and the amount of U.S. exports. As world prices increase relative to domestic prices, U.S. exports rise.

U.S. Import Demand If the world price is below the domestic \$1 price, the United States will import aluminum. Consider a \$0.75 world price. The supply curve in Figure 40.3a reveals that at that price U.S. firms produce only 75 million pounds of aluminum. But the demand curve shows that the United States wants to buy 125 million pounds at that price. The result is a domestic shortage of 50 million pounds. To satisfy that shortage, the United States will import 50 million pounds of aluminum.

At an even lower world price, \$0.50, U.S. producers will supply only 50 million pounds. Because U.S. consumers want to buy 150 million pounds at that price, there is a domestic shortage of 100 million pounds. Imports will flow to the United States to make up the difference. That is, at a \$0.50

world price U.S. firms will supply 50 million pounds and 100 million pounds will be imported.

In Figure 40.3b, we plot the U.S. **import demand curve** from these data. This *downsloping curve* shows the amounts of aluminum that will be imported at world prices below the \$1 U.S. domestic price. The relationship between world prices and imported amounts is inverse or negative. At a world price of \$1, domestic output will satisfy U.S. demand; imports will be zero (point *a*). But at \$0.75 the United States will import 50 million pounds of aluminum (point *x*); at \$0.50, the United States will import 100 million pounds (point *y*). Connecting points *a*, *x*, and *y* yields the *downsloping* U.S. import demand curve. It reveals that as world prices fall relative to U.S. domestic prices, U.S. imports increase.

Supply and Demand in Canada

We repeat our analysis in Figure 40.4, this time from the viewpoint of Canada. (We have converted Canadian dollar prices to U.S. dollar prices via the exchange rate.) Note that the domestic supply curve S_d and the domestic demand curve D_d for aluminum in Canada yield a domestic price of \$0.75, which is \$0.25 lower than the \$1 U.S. domestic price.

The analysis proceeds exactly as above except that the domestic price is now the Canadian price. If the world price is \$0.75, Canadians will neither export nor import aluminum

FIGURE 40.4 Canadian export supply and import demand. (a) At world prices above the \$0.75 domestic price, production in Canada exceeds domestic consumption. At world prices below \$0.75, domestic shortages occur. (b) Surpluses result in exports, and shortages result in imports. The Canadian export supply curve and import demand curve depict the relationships between world prices and exports or imports.

(giving us point q in Figure 40.4b). At world prices above \$0.75, Canadian firms will produce more aluminum than Canadian consumers will buy. Canadian firms will export the surplus. At a \$1 world price, Figure 40.4b tells us that Canada will have and export a domestic surplus of 50 million pounds (yielding point r). At \$1.25, it will have and will export a domestic surplus of 100 million pounds (point s). Connecting these points yields the upsloping Canadian export supply curve, which reflects the domestic surpluses (and hence the exports) that occur when the world price exceeds the \$0.75 Canadian domestic price.

At world prices below \$0.75, domestic shortages occur in Canada. At a \$0.50 world price, Figure 40.4a shows that Canadian consumers want to buy 125 million pounds of aluminum but Canadian firms will produce only 75 million pounds. The shortage will bring 50 million pounds of imports to Canada (point t in Figure 40.4b). The Canadian import demand curve in that figure shows the Canadian imports that will occur at all world aluminum prices below the \$0.75 Canadian domestic price.

Equilibrium World Price, Exports, and Imports

We now have the tools for determining the **equilibrium world price** of aluminum and the equilibrium world levels of exports and imports when the world is opened to trade. Figure 40.5 combines the U.S. export supply curve and import

FIGURE 40.5 Equilibrium world price and quantity of exports and imports. In a two-nation world, the equilibrium world price (= \$0.88) is determined by the intersection of one nation's export supply curve and the other nation's import demand curve. This intersection also decides the equilibrium volume of exports and imports. Here, Canada exports 25 million pounds of aluminum to the United States.

demand curve in Figure 40.3b and the Canadian export supply curve and import demand curve in Figure 40.4b. The two U.S. curves proceed rightward from the \$1 U.S. domestic price; the two Canadian curves proceed rightward from the \$0.75 Canadian domestic price.

International equilibrium occurs in this two-nation model where one nation's import demand curve intersects another nation's export supply curve. In this case, the U.S. import demand curve intersects Canada's export supply curve at e . There, the world price of aluminum is \$0.88. The Canadian export supply curve indicates that Canada will export 25 million pounds of aluminum at this price. Also at this price the United States will import 25 million pounds from Canada, indicated by the U.S. import demand curve. The \$0.88 world price equates the quantity of imports demanded and the quantity of exports supplied (25 million pounds). Thus, there will be world trade of 25 million pounds of aluminum at \$0.88 per pound.

Note that after trade, the single \$0.88 world price will prevail in both Canada and the United States. Only one price for a standardized commodity can persist in a highly competitive world market. With trade, all consumers can buy a pound of aluminum for \$0.88, and all producers can sell it for that price. This world price means that Canadians will pay more for aluminum with trade (\$0.88) than without it (\$0.75). The increased Canadian output caused by trade raises Canadian per-unit production costs and therefore raises the price of aluminum in Canada. The United States, however, pays less for aluminum with trade (\$0.88) than without it (\$1). The U.S. gain comes from Canada's comparative cost advantage in producing aluminum.

Why would Canada willingly send 25 million pounds of its aluminum output to the United States for U.S. consumption? After all, producing this output uses up scarce Canadian resources and drives up the price of aluminum for Canadians. Canadians are willing to export aluminum to the United States because Canadians gain the means—the U.S. dollars—to import other goods, say, computer software, from the United States. Canadian exports enable Canadians to acquire imports that have greater value to Canadians than the exported aluminum. Canadian exports to the United States finance Canadian imports from the United States.

QUICK REVIEW 40.4

- ✓ A nation will export a particular product if the world price exceeds the domestic price; it will import the product if the world price is less than the domestic price.
- ✓ In a two-country world model, equilibrium world prices and equilibrium quantities of exports and imports occur where one nation's export supply curve intersects the other nation's import demand curve.

Trade Barriers and Export Subsidies

LO40.4 Analyze the economic effects of tariffs and quotas.

While a nation as a whole gains from trade, trade may harm particular domestic industries and their workers. Those industries might seek to preserve their economic positions by persuading their respective governments to protect them from imports—perhaps through tariffs, import quotas, or other trade barriers.

Indeed, the public may be won over by the apparent plausibility (“Cut imports and prevent domestic unemployment”) and the patriotic ring (“Buy American!”) of the arguments. The alleged benefits of tariffs are immediate and clear-cut to the public, but the adverse effects cited by economists are obscure and dispersed over the entire economy. When political deal-making is added in—“You back tariffs for the apparel industry in my state, and I’ll back tariffs for the auto industry in your state”—the outcome can be a politically robust network of trade barriers. These impediments to free international trade can take several forms.

Tariffs are excise taxes or “duties” on the dollar values or physical quantities of imported goods. They may be imposed to obtain revenue or to protect domestic firms. A **revenue tariff** is usually applied to a product that is not being produced domestically, for example, tin, coffee, or bananas in the case of the United States. Rates on revenue tariffs tend to be modest and are designed to provide the federal government with revenue. A **protective tariff** is implemented to shield domestic producers from foreign competition. These tariffs impede free trade by increasing the prices of imported goods and therefore shifting sales toward domestic producers. Although protective tariffs are usually not high enough to stop the importation of foreign goods, they put foreign producers at a competitive disadvantage. A tariff on imported auto tires, for example, would make domestically produced tires more attractive to consumers.

An **import quota** is a limit on the quantities or total values of specific items that are imported in some period. Once a quota is filled, further imports of that product are choked off. Import quotas are more effective than tariffs in impeding international trade. With a tariff, a product can go on being imported in large quantities. But with an import quota, all imports are prohibited once the quota is filled.

A **nontariff barrier (NTB)** includes onerous licensing requirements, unreasonable standards pertaining to product quality, or simply bureaucratic hurdles and delays in customs procedures. Some nations require that importers of foreign goods obtain licenses and then restrict the number of licenses issued. Although many nations carefully inspect imported agricultural products to prevent the introduction of potentially

Buy American?

Will “buying American” make Americans better off? No, says Dallas Federal Reserve economist W. Michael Cox:

A common myth is that it is better for Americans to spend their money at home than abroad. The best way to expose the fallacy of this argument is to take it to its logical extreme. If it is better for me to spend my money here than abroad,

then it is even better yet to buy in Texas than in New York, better yet to buy in Dallas than in Houston . . . in my own neighborhood . . . within my own family . . . to consume only what I can produce. Alone and poor.*

harmful insects, some countries use lengthy inspections to impede imports. Japan and the European countries frequently require that their domestic importers of foreign goods obtain licenses. By restricting the issuance of licenses, governments can limit imports.

A **voluntary export restriction (VER)** is a trade barrier by which foreign firms “voluntarily” limit the amount of their exports to a particular country. VERs have the same effect as import quotas and are agreed to by exporters to avoid more stringent tariffs or quotas. In the late 1990s, for example, Canadian producers of softwood lumber (fir, spruce, cedar, pine) agreed to a VER on exports to the United States under the threat of a permanently higher U.S. tariff.

An **export subsidy** consists of a government payment to a domestic producer of export goods and is designed to aid that producer. By reducing production costs, the subsidies enable the domestic firm to charge a lower price and thus to sell more exports in world markets. Two examples: Some European governments have heavily subsidized Airbus Industries, a European firm that produces commercial aircraft. The subsidies help Airbus compete against the American firm Boeing. The United States and other nations have subsidized domestic farmers to boost the domestic food supply. Such subsidies have artificially lowered export prices on agricultural produce.

Later in this chapter we will discuss some of the specific arguments and appeals that are made to justify protection.

Economic Impact of Tariffs

We will confine our in-depth analysis of the effects of trade barriers to the two most common forms: tariffs and quotas. Once again, we turn to supply and demand analysis for help. Curves D_d and S_d in Figure 40.6 show domestic demand and supply for a product in which a nation, say, the United States, does *not* have a comparative advantage—for example, smartphones. (Disregard curve $S_d + Q$ for now.) Without world trade, the domestic price and output would be P_d and q , respectively.

Assume now that the domestic economy is opened to world trade and that China, which *does* have a comparative advantage in smartphones, begins to sell its smartphones in the United States. We assume that with free trade the domestic price cannot differ from the world price, which here is P_w . At P_w , domestic consumption is d and domestic production is a . The horizontal distance between the domestic supply and demand curves at P_w represents imports of ad . Thus far, our analysis is similar to the analysis of world prices in Figure 40.3.

Direct Effects Suppose now that the United States imposes a tariff on each imported smartphone. The tariff, which raises the price of imported smartphones from P_w to P_t , has four effects:

- **Decline in consumption** Consumption of smartphones in the United States declines from d to c as the higher price moves buyers up and to the left along their

FIGURE 40.6 The economic effects of a protective tariff or an import quota. A tariff that increases the price of a good from P_w to P_t will reduce domestic consumption from d to c . Domestic producers will be able to sell more output (b rather than a) at a higher price (P_t rather than P_w). Foreign exporters are injured because they sell less output (bc rather than ad). The yellow area indicates the amount of tariff paid by domestic consumers. An import quota of bc units has the same effect as the tariff, with one exception: The amount represented by the yellow area will go to foreign producers rather than to the domestic government.

demand curve. The tariff prompts consumers to buy fewer smartphones and reallocate a portion of their expenditures to less desired substitute products. U.S. consumers are clearly injured by the tariff, since they pay $P_t - P_w$ more for each of the c units they buy at price P_t .

- **Increased domestic production** U.S. producers—who are not subject to the tariff—receive the higher price P_t per unit. Because this new price is higher than the pretariff world price P_w , the domestic smartphone industry moves up and to the right along its supply curve S_d , increasing domestic output from a to b . Domestic producers thus enjoy both a higher price and expanded sales; this explains why domestic producers lobby for protective tariffs. But from a social point of view, the increase in domestic production from a to b means that the tariff permits domestic producers of smartphones to bid resources away from other, more efficient, U.S. industries.
- **Decline in imports** Chinese producers are hurt. Although the sales price of each smartphone is higher by $P_t - P_w$, that amount accrues to the U.S. government, not to Chinese producers. The after-tariff world price, or the per-unit revenue to Chinese producers, remains at P_w , but the volume of U.S. imports (Chinese exports) falls from ad to bc .
- **Tariff revenue** The yellow rectangle represents the amount of revenue the tariff yields. Total revenue from the tariff is determined by multiplying the tariff, $P_t - P_w$ per unit, by the number of smartphones imported, bc . This tariff revenue is a transfer of income from consumers to government and does not represent any net change in the nation's economic well-being. The result is that government gains this portion of what consumers lose by paying more for smartphones.

Indirect Effect Tariffs have a subtle effect beyond what our supply and demand diagram can show. Because China sells fewer smartphones in the United States, it earns fewer dollars and so must buy fewer U.S. exports. U.S. export industries must then cut production and release resources. These are highly efficient industries, as we know from their comparative advantage and their ability to sell goods in world markets.

Tariffs directly promote the expansion of inefficient industries that do not have a comparative advantage; they also indirectly cause the contraction of relatively efficient industries that do have a comparative advantage. Put bluntly, tariffs cause resources to be shifted in the wrong direction—and that is not surprising. We know that specialization and world trade lead to more efficient use of world resources and greater world output. But protective

tariffs reduce world trade. Therefore, tariffs also reduce efficiency and the world's real output.

Economic Impact of Quotas

We noted earlier that an import quota is a legal limit placed on the amount of some product that can be imported in a given year. Quotas have the same economic impact as a tariff, with one big difference: While tariffs generate revenue for the domestic government, a quota transfers that revenue to foreign producers.

Suppose in Figure 40.6 that, instead of imposing a tariff, the United States prohibits any imports of Chinese smartphones in excess of bc units. In other words, an import quota of bc smartphones is imposed on China. We deliberately chose the size of this quota to be the same amount as imports would be under a $P_t - P_w$ tariff so that we can compare “equivalent” situations. As a consequence of the quota, the supply of smartphones is $S_d + Q$ in the United States. This supply consists of the domestic supply plus the fixed amount bc ($= Q$) that importers will provide at each domestic price. The supply curve $S_w + Q$ does not extend below price P_w because Chinese producers would not export smartphones to the United States at any price below P_w ; instead, they would sell them to other countries at the world market price of P_w .

Most of the economic results are the same as those with a tariff. Prices of smartphones are higher (P_t instead of P_w) because imports have been reduced from ad to bc . Domestic consumption of smartphones is down from d to c . U.S. producers enjoy both a higher price (P_t rather than P_w) and increased sales (b rather than a).

The difference is that the price increase of $P_t - P_w$ paid by U.S. consumers on imports of bc —the yellow area—no longer goes to the U.S. Treasury as tariff (tax) revenue but flows to the Chinese firms that have acquired the quota rights to sell smartphones in the United States. For consumers in the United States, a tariff produces a better economic outcome than a quota, other things being the same. A tariff generates government revenue that can be used to cut other taxes or to finance public goods and services that benefit the United States. In contrast, the higher price created by quotas results in additional revenue for foreign producers.

QUICK REVIEW 40.5

- ✓ A tariff on a product increases its price, reduces its consumption, increases its domestic production, reduces its imports, and generates tariff revenue for the government.
- ✓ An import quota does the same, except a quota generates revenue for foreign producers rather than for the government imposing the quota.

Net Costs of Tariffs and Quotas

Figure 40.6 shows that tariffs and quotas impose costs on domestic consumers but provide gains to domestic producers and, in the case of tariffs, revenue to the federal government. The consumer costs of trade restrictions are calculated by determining the effect the restrictions have on consumer prices. Protection raises the price of a product in three ways: (1) The price of the imported product goes up; (2) the higher price of imports causes some consumers to shift their purchases to higher-priced domestically produced goods; and (3) the prices of domestically produced goods rise because import competition has declined.

Study after study finds that the costs to consumers substantially exceed the gains to producers and government. A sizable net cost or efficiency loss to society arises from trade protection. Furthermore, industries employ large amounts of economic resources to influence Congress to pass and retain protectionist laws. Because these rent-seeking efforts divert resources away from more socially desirable purposes, trade restrictions impose these additional costs on society as well.

Conclusion: The gains that U.S. trade barriers create for protected industries and their workers come at the expense of much greater losses for the entire economy. The result is economic inefficiency, reduced consumption, and lower standards of living.

The Case for Protection: A Critical Review

L040.5 Analyze the validity of the most frequently presented arguments for protectionism.

Despite the logic of specialization and trade, there are still protectionists in some union halls, corporate boardrooms, and congressional conference rooms. What arguments do protectionists make to justify trade barriers? How valid are those arguments?

Military Self-Sufficiency Argument

The argument here is not economic but political-military: Protective tariffs are needed to preserve or strengthen industries that produce the materials essential for national defense. In an uncertain world, the political-military objectives (self-sufficiency) sometimes must take precedence over economic goals (efficiency in the use of world resources).

Unfortunately, it is difficult to measure and compare the benefit of increased national security against the cost of economic inefficiency when protective tariffs are imposed. The economist can only point out that when a nation levies tariffs to increase military self-sufficiency, it incurs economic costs.

All people in the United States would agree that relying on hostile nations for necessary military equipment is not a

good idea, yet the self-sufficiency argument is open to serious abuse. Nearly every industry can claim that it makes direct or indirect contributions to national security and hence deserves protection from imports.

Diversification-for-Stability Argument

Highly specialized economies such as Saudi Arabia (based on oil) and Cuba (based on sugar) are dependent on international markets for their income. In these economies, wars, international political developments, recessions abroad, and random fluctuations in world supply and demand for one or two particular goods can cause deep declines in export revenues and therefore in domestic income. Tariff and quota protection are allegedly needed in such nations to enable greater industrial diversification. That way, these economies will not be so dependent on exporting one or two products to obtain the other goods they need. Such goods will be available domestically, thereby providing greater domestic stability.

There is some truth in this diversification-for-stability argument. But the argument has little or no relevance to the United States and other advanced economies. Also, the economic costs of diversification may be great; for example, one-crop economies may be highly inefficient at manufacturing.

Infant Industry Argument

The infant industry argument contends that protective tariffs are needed to allow new domestic industries to establish themselves. Temporarily shielding young domestic firms from the severe competition of more mature and more efficient foreign firms will give infant industries a chance to develop and become efficient producers.

This argument for protection rests on an alleged exception to the case for free trade. The exception is that young industries have not had, and if they face mature foreign competition will never have, the chance to make the long-run adjustments needed for larger scale and greater efficiency in production. In this view, tariff protection for such infant industries will correct a misallocation of world resources perpetuated by historically different levels of economic development between domestic and foreign industries.

There are some logical problems with the infant industry argument. In the developing nations, it is difficult to determine which industries are the infants that are capable of achieving economic maturity and therefore deserving protection. Also, protective tariffs may persist even after industrial maturity has been realized.

Most economists feel that if infant industries are to be subsidized, there are better means than tariffs for doing so. Direct subsidies, for example, have the advantage of making explicit which industries are being aided and to what degree.

Protection-against-Dumping Argument

The protection-against-dumping argument contends that tariffs are needed to protect domestic firms from “dumping” by foreign producers. **Dumping** is the sale of a product in a foreign country at prices either below cost or below the prices commonly charged at home.

Economists cite two plausible reasons for this behavior. First, with regard to below-cost dumping, firms in country A may dump goods at below cost into country B in an attempt to drive their competitors in country B out of business. If the firms in country A succeed in driving their competitors in country B out of business, they will enjoy monopoly power and monopoly prices and profits on the goods they subsequently sell in country B. Their hope is that the longer-term monopoly profits will more than offset the losses from below-cost sales that must take place while they are attempting to drive their competitors in country B out of business.

Second, dumping that involves selling abroad at a price that is below the price commonly charged in the home country (but that is still at or above production costs) may be a form of price discrimination, which is charging different prices to different customers. As an example, a foreign seller that has a monopoly in its home market may find that it can maximize its overall profit by charging a high price in its monopolized domestic market while charging a lower price in the United States, where it must compete with U.S. producers. Curiously, it may pursue this strategy even if it makes no profit at all from its sales in the United States, where it must charge the competitive price. So why bother selling in the United States? Because the increase in overall production that comes about by exporting to the United States may allow the firm to obtain the per-unit cost savings often associated with large-scale production. These cost savings imply even higher profits in the monopolized domestic market.

Because dumping is an “unfair trade practice,” most nations prohibit it. For example, where dumping is shown to injure U.S. firms, the federal government imposes tariffs called *antidumping duties* on the goods in question. But relatively few documented cases of dumping occur each year, and specific instances of unfair trade do not justify widespread, permanent tariffs. Moreover, antidumping duties can be abused. Often, what appears to be dumping is simply comparative advantage at work.

Increased Domestic Employment Argument

Arguing for a tariff to “save U.S. jobs” becomes fashionable when the economy encounters a recession (such as the severe recession of 2007–2008 in the United States). In an economy that engages in international trade, exports involve spending on domestic output and imports reflect spending to obtain part of another nation’s output. So, in this argument, reducing imports will divert spending on another nation’s output to spending on

domestic output. Thus, domestic output and employment will rise. But this argument has several shortcomings.

While imports may eliminate some U.S. jobs, they create others. Imports may have eliminated the jobs of some U.S. steel and textile workers in recent years, but other workers have gained jobs unloading ships, flying imported aircraft, and selling imported electronic equipment. Import restrictions alter the composition of employment, but they may have little or no effect on the volume of employment.

The *fallacy of composition*—the false idea that what is true for the part is necessarily true for the whole—is also present in this rationale for tariffs. All nations cannot simultaneously succeed in restricting imports while maintaining their exports; what is true for one nation is not true for all nations. The exports of one nation must be the imports of another nation. To the extent that one country is able to expand its economy through an excess of exports over imports, the resulting excess of imports over exports worsens another economy's unemployment problem. It is no wonder that tariffs and import quotas meant to achieve domestic full employment are called “beggar my neighbor” policies: They achieve short-run domestic goals by making trading partners poorer.

Moreover, nations adversely affected by tariffs and quotas are likely to retaliate, causing a “trade war” (more precisely, a *trade barrier war*) that will choke off trade and make all nations worse off. The **Smoot-Hawley Tariff Act** of 1930 is a classic example. Although that act was meant to reduce imports and stimulate U.S. production, the high tariffs it authorized prompted adversely affected nations to retaliate with tariffs equally high. International trade fell, lowering the output and income of all nations. Economic historians generally agree that the Smoot-Hawley Tariff Act was a contributing cause of the Great Depression.

Finally, forcing an excess of exports over imports cannot succeed in raising domestic employment over the long run. It is through U.S. imports that foreign nations earn dollars for buying U.S. exports. In the long run, a nation must import in order to export. The long-run impact of tariffs is not an increase in domestic employment but, at best, a reallocation of workers away from export industries and to protected domestic industries. This shift implies a less efficient allocation of resources.

Cheap Foreign Labor Argument

The cheap foreign labor argument says that domestic firms and workers must be shielded from the ruinous competition of countries where wages are low. If protection is not provided, cheap imports will flood U.S. markets and the prices of U.S. goods—along with the wages of U.S. workers—will be pulled down. That is, domestic living standards in the United States will be reduced.

This argument can be rebutted at several levels. The logic of the argument suggests that it is not mutually beneficial for

rich and poor persons to trade with one another. However, that is not the case. A low-income farmworker may pick lettuce or tomatoes for a rich landowner, and both may benefit from the transaction. And both U.S. consumers and Chinese workers gain when they “trade” a pair of athletic shoes priced at \$30 as opposed to U.S. consumers being restricted to buying a similar shoe made in the United States for \$60.

Also, recall that gains from trade are based on comparative advantage, not on absolute advantage. Look back at Figure 40.1, where we supposed that the United States and Mexico had labor forces of exactly the same size. Noting the positions of the production possibilities curves, observe that U.S. labor can produce more of either good. Thus, it is more productive. Because of this greater productivity, we can expect wages and living standards to be higher for U.S. labor. Mexico's less productive labor will receive lower wages.

The cheap foreign labor argument suggests that, to maintain its standard of living, the United States should not trade with low-wage Mexico. What if it does not trade with Mexico? Will wages and living standards rise in the United States as a result? No. To obtain vegetables, the United States will have to reallocate a portion of its labor from its relatively more-efficient beef industry to its relatively less-efficient vegetables industry. As a result, the average productivity of U.S. labor will fall, as will real wages and living standards. The labor forces of both countries will have diminished standards of living because without specialization and trade they will have less output available to them. Compare column 4 with column 1 in Table 40.1 or points A' and Z' with A and Z in Figure 40.2 to confirm this point.

Another problem with the cheap foreign labor argument is that its proponents incorrectly focus on labor costs per hour when what really matters is labor costs per unit of output. As an example, suppose that a U.S. factory pays its workers \$20 per hour while a factory in a developing country pays its workers \$4 per hour. The proponents of the cheap foreign labor argument look at these numbers and conclude—incorrectly—that it is impossible for the U.S. factory to compete with the factory in the developing country. But this conclusion fails to take into account two crucial facts:

- What actually matters is labor costs *per unit of output*, not labor costs *per hour of work*.
- Differences in productivity typically mean that labor costs per unit of output are often nearly identical despite huge differences in hourly labor costs.

To see why these points matter so much, let's take into account how productive the two factories are. Because the U.S. factory uses much more sophisticated technology, better-trained workers, and a lot more capital per worker, one worker in one hour can produce 20 units of output. Since the U.S. workers get paid \$20 per hour, this means the U.S. factory's labor cost *per unit of output* is \$1. The factory in the developing country is

much less productive since it uses less efficient technology and its relatively untrained workers have a lot less machinery and equipment to work with. A worker there produces only 4 units per hour. Given the foreign wage of \$4 per hour, this means that the labor cost per unit of output at the factory in the developing country is also \$1.

As you can see, the lower wage rate per hour at the factory in the developing country does not translate into lower labor costs per unit—meaning that it won't be able to undersell its U.S. competitor just because its workers get paid lower wages per hour.

Proponents of the cheap foreign labor argument tend to focus exclusively on the large international differences that exist in labor costs per hour. They typically fail to mention that these differences in labor costs per hour are mostly the result of tremendously large differences in productivity and that these large differences in productivity serve to equalize labor costs per unit of output. As a result, firms in developing countries only *sometimes* have an advantage in terms of labor costs per unit of output. Whether they do in any specific situation will vary by industry and firm and will depend on differences in productivity as well as differences in labor costs per hour. For many goods, labor productivity in high-wage countries like the United States is so much higher than labor productivity in low-wage countries that it is actually cheaper *per unit of output* to manufacture those goods in high-wage countries. That is why, for instance, Intel still makes microchips in the United States and why most automobiles are still produced in the United States, Japan, and Europe rather than in low-wage countries.

QUICK REVIEW 40.6

- ✓ Most rationales for trade protections are special-interest requests that, if followed, would create gains for protected industries and their workers at the expense of greater losses for the economy.

Multilateral Trade Agreements and Free-Trade Zones

LO40.6 Identify and explain the objectives of GATT, WTO, EU, eurozone, and NAFTA and discuss offshoring and trade adjustment assistance.

Aware of the detrimental effects of trade wars and the general weaknesses of arguments for trade protections, nations have worked to lower tariffs worldwide. Their pursuit of freer trade has been aided by recently emerged special-interest groups that have offset the more-established special-interest groups that have traditionally supported tariffs and quotas. Specifically, lower tariffs are now supported by exporters of goods and services, importers of foreign components used in “domestic” products, and domestic sellers of imported products.

General Agreement on Tariffs and Trade

In 1947, 23 nations, including the United States, signed the **General Agreement on Tariffs and Trade (GATT)**. GATT was based on three principles: (1) equal, nondiscriminatory trade treatment for all member nations; (2) the reduction of tariffs by multilateral negotiation; and (3) the elimination of import quotas. Basically, GATT provided a forum for the multilateral negotiation of reduced trade barriers.

Since the Second World War, member nations have completed eight “rounds” of GATT negotiations to reduce trade barriers. The eighth round of negotiations began in Uruguay in 1986. After seven years of complex discussions, in 1993 a new agreement was reached by the 128 nations that were by that time members of GATT. The Uruguay Round agreement took effect on January 1, 1995, and its provisions were phased in through 2005.

Under this agreement, tariffs on thousands of products were eliminated or reduced, with overall tariffs dropping by 33 percent. The agreement also liberalized government rules that in the past impeded the global market for such services as advertising, legal services, tourist services, and financial services. Quotas on imported textiles and apparel were phased out and replaced with tariffs. Other provisions reduced agricultural subsidies paid to farmers and protected intellectual property (patents, trademarks, and copyrights) against piracy.

World Trade Organization

The Uruguay Round agreement established the **World Trade Organization (WTO)** as GATT's successor. Some 161 nations belonged to the WTO in 2015. The WTO oversees trade agreements reached by the member nations, and rules on trade disputes among them. It also provides forums for further rounds of trade negotiations. The ninth and latest round of negotiations—the **Doha Development Agenda**—was launched in Doha, Qatar, in late 2001. (The trade rounds occur over several years in several venues but are named after the city or country of origination.) The negotiations are aimed at further reducing tariffs and quotas, as well as agricultural subsidies that distort trade. You can get an update on the status of the complex negotiations at www.wto.org.

GATT and the WTO have been positive forces in the trend toward liberalized world trade. The trade rules agreed upon by the member nations provide a strong and necessary bulwark against the protectionism called for by the special-interest groups in the various nations.

For that reason and others, the WTO is quite controversial. Critics are concerned that rules crafted to expand international trade and investment enable firms to circumvent national laws that protect workers and the environment. Critics ask: What good are minimum-wage laws, worker-safety laws, collective-bargaining rights, and environmental laws if firms can easily shift their production to nations that have weaker laws or if consumers can buy goods produced in those countries?

Proponents of the WTO respond that labor and environmental protections should be pursued directly in nations that have low standards and via international organizations other than the WTO. These issues should not be linked to the process of trade liberalization, which confers widespread economic benefits across nations. Moreover, say proponents of the WTO, many environmental and labor concerns are greatly overblown. Most world trade is among advanced industrial countries, not between them and countries that have lower environmental and labor standards. Moreover, the free flow of goods and resources raises output and income in the developing nations. Historically, such increases in living standards have eventually resulted in stronger, not weaker, protections for the environment and for workers.

The European Union

Countries have also sought to reduce tariffs by creating regional free-trade zones. The most dramatic example is the **European Union (EU)**. Initiated in 1958 as the Common Market, in 2003 the EU comprised 15 European nations—Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, the Netherlands, Portugal, Spain, Sweden, and the United Kingdom. In 2004, the EU expanded by 10 additional European countries—Cyprus, the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, and Slovenia. The 2007 addition of Bulgaria and Romania plus the 2013 addition of Croatia expanded the EU to 28 nations.

The EU has abolished tariffs and import quotas on nearly all products traded among the participating nations and established a common system of tariffs applicable to all goods received from nations outside the EU. It has also liberalized the movement of capital and labor within the EU and has created common policies in other economic matters of joint concern, such as agriculture, transportation, and business practices.

EU integration has achieved for Europe what the U.S. constitutional prohibition on tariffs by individual states has achieved for the United States: increased regional specialization, greater productivity, greater output, and faster economic growth. The free flow of goods and services has created large markets for EU industries. The resulting economies of large-scale production have enabled these industries to achieve much lower costs than they could have achieved in their small, single-nation markets.

One of the most significant accomplishments of the EU was the establishment of the so-called **eurozone** or euro area in the early 2000s. As of 2015, 19 members of the EU (Austria, Belgium, Cyprus, Estonia, Finland, France, Germany, Greece, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Portugal, Slovenia, Slovakia, and Spain) use the euro as a common currency. Notably, the United Kingdom, Denmark, and Sweden have opted not to use the common currency, at least for now. But gone are French francs,

German marks, Italian liras, and other national currencies that were once used by eurozone countries.

Economists expect the adoption of the euro to raise the standard of living in the eurozone nations over time. By ending the inconvenience and expense of exchanging currencies, the euro has enhanced the free flow of goods, services, and resources among the eurozone members. Companies that previously sold products in only one or two European nations have found it easier to price and sell their products in all 19 eurozone countries. The euro has also allowed consumers and businesses to comparison shop for outputs and inputs, and this capability has increased competition, reduced prices, and lowered costs.

North American Free Trade Agreement

In 1993 Canada, Mexico, and the United States created a major free-trade zone. The **North American Free Trade Agreement (NAFTA)** established a free-trade area that has about the same combined output as the EU but encompasses a much larger geographic area. NAFTA has eliminated tariffs and other trade barriers among Canada, Mexico, and the United States for most goods and services.

Critics of NAFTA feared that it would cause a massive loss of U.S. jobs as firms moved to Mexico to take advantage of lower wages and weaker regulations on pollution and workplace safety. Also, they were concerned that Japan and South Korea would build plants in Mexico and transport goods tariff-free to the United States, further hurting U.S. firms and workers.

In retrospect, critics were much too pessimistic. Since the passage of NAFTA in 1993, employment in the United States has increased by more than 25 million workers. NAFTA has increased trade among Canada, Mexico, and the United States and has enhanced the standard of living in all three countries.

QUICK REVIEW 40.7

- ✓ The General Agreement on Tariffs and Trade (GATT) of 1947 reduced tariffs and quotas and established a process for numerous subsequent rounds of multinational trade negotiations that have liberalized international trade.
- ✓ The World Trade Organization (WTO)—GATT's successor—rules on trade disputes and provides forums for negotiations on further rounds of trade liberalization. The current round of negotiations is called the Doha Development Agenda.
- ✓ The European Union (EU) and the North American Free Trade Agreement (NAFTA) have reduced internal trade barriers among their member nations by establishing multinational free-trade zones.

Recognizing Those Hurt by Free Trade

Shifts in patterns of comparative advantage and removal of long-standing trade protection can hurt specific groups of workers. For example, the erosion of the United States' once strong comparative advantage in steel has caused production plant shutdowns and layoffs in the U.S. steel industry. The textile and apparel industries in the United States face similar difficulties. Clearly, not everyone wins from free trade (or freer trade). Some workers lose.

Trade Adjustment Assistance

The **Trade Adjustment Assistance Act** of 2002 introduced some innovative policies to help those hurt by shifts in international trade patterns. The law provides cash assistance (beyond unemployment insurance) for up to 78 weeks for workers displaced by imports or plant relocations abroad. To obtain the assistance, workers must participate in job searches, training programs, or remedial education. Also provided are relocation allowances to help displaced workers move geographically to new jobs within the United States. Refundable tax credits for health insurance serve as payments to help workers maintain their insurance coverage during the retraining and job-search period. Workers who are 50 years of age or older are eligible for “wage insurance,” which replaces some of the difference in pay (if any) between their old and new jobs. Many economists support trade adjustment assistance because it not only helps workers hurt by international trade but also helps create the political support necessary to reduce trade barriers and export subsidies.

But not all economists favor trade adjustment assistance. Loss of jobs from imports, sending some work abroad, and plant relocations to other countries are only a small fraction (about 4 percent in recent years) of total job losses in the economy each year. Many workers also lose their jobs because of changing patterns of demand, changing technology, bad management, and other dynamic aspects of a market economy. Some critics ask, “What makes losing one’s job to international trade worthy of such special treatment, compared to losing one’s job to, say, technological change or domestic competition?” Economists can find no totally satisfying answer.

Offshoring of Jobs

Not only are some U.S. jobs lost because of international trade, but some are lost because of globalization of resource markets. In recent years, U.S. firms have found the outsourcing of work abroad to be increasingly profitable. Economists call this business activity **offshoring**—shifting work previously done by American workers to workers located in other nations. Offshoring is not a new practice but traditionally has

involved components for U.S. manufacturing goods. For example, Boeing has long offshored the production of major airplane parts for its “American” aircraft.

Recent advances in computer and communications technology have enabled U.S. firms to offshore service jobs such as data entry, book composition, software coding, call-center operations, medical transcription, and claims processing to countries such as India. Where offshoring occurs, some of the value added in the production process accrues to foreign countries rather than the United States. So part of the income generated from the production of U.S. goods is paid to foreigners, not to American workers.

Offshoring is a wrenching experience for many Americans who lose their jobs, but it is not necessarily bad for the overall economy. Offshoring simply reflects growing specialization and international trade in services, or, more descriptively, “tasks.” That growth has been made possible by recent trade agreements and new information and communication technologies. As with trade in goods, trade in services reflects comparative advantage and is beneficial to both trading parties. Moreover, the United States has a sizable trade surplus with other nations in services. The United States gains by specializing in high-valued services such as transportation services, accounting services, legal services, and advertising services, where it still has a comparative advantage. It then “trades” to obtain lower-valued services such as call-center and data-entry work, for which comparative advantage has gone abroad.

Offshoring also increases the demand for complementary jobs in the United States. Jobs that are close substitutes for existing U.S. jobs are lost, but complementary jobs in the United States are expanded. For example, the lower price of writing software code in India may mean a lower cost of software sold in the United States and abroad. That, in turn, may create more jobs for U.S.-based workers such as software designers, marketers, and distributors. Moreover, offshoring may encourage domestic investment and the expansion of firms in the United States by reducing their production costs and keeping them competitive worldwide. In some instances, “offshoring jobs” may equate to “importing competitiveness.” Entire firms that might otherwise disappear abroad may remain profitable in the United States only because they can offshore some of their work.

QUICK REVIEW 40.8

- ✓ Increased international trade and offshoring of jobs have harmed some specific U.S. workers and have led to policies such as trade adjustment assistance to try to help them with their transitions to new lines of work.

Petition of the Candlemakers, 1845

French Economist Frédéric Bastiat (1801–1850) Devastated the Proponents of Protectionism by Satirically Extending Their Reasoning to Its Logical and Absurd Conclusions.

Petition of the Manufacturers of Candles, Waxlights, Lamps, Candlesticks, Street Lamps, Snuffers, Extinguishers, and of the Producers of Oil Tallow, Rosin, Alcohol, and, Generally, of Everything Connected with Lighting.

TO MESSIEURS THE MEMBERS OF THE CHAMBER OF DEPUTIES.

Gentlemen—You are on the right road. You reject abstract theories, and have little consideration for cheapness and plenty. Your chief care is the interest of the producer. You desire to emancipate him from external competition, and reserve the national market for national industry.

We are about to offer you an admirable opportunity of applying your—what shall we call it? your theory? No; nothing is more deceptive than theory; your doctrine? your system? your principle? but you dislike doctrines, you abhor systems, and as for principles, you deny that there are any in social economy: we shall say, then, your practice, your practice without theory and without principle.

We are suffering from the intolerable competition of a foreign rival, placed, it would seem, in a condition so far superior to ours for the production of light, that he absolutely inundates our national market with it at a price fabulously reduced. The moment he shows himself, our trade leaves us—all consumers apply to him; and a branch of native industry, having countless ramifications, is all at once rendered completely stagnant. This rival . . . is no other than the Sun.

What we pray for is, that it may please you to pass a law ordering the shutting up of all windows, skylights, dormer windows, outside and inside shutters, curtains, blinds, bull's-eyes; in a word, of all openings, holes, chinks, clefts, and fissures, by or through which the light of the sun has been in use to enter houses, to the prejudice of the meritorious manufacturers with which we flatter ourselves we have accommodated our country,—a country which, in gratitude, ought not to abandon us now to a strife so unequal.

If you shut up as much as possible all access to natural light, and create a demand for artificial light, which of our French manufacturers will not be encouraged by it? If more tallow is consumed, then there must be more oxen and sheep; and, consequently, we shall behold the multiplication of artificial meadows, meat, wool, hides, and, above all, manure, which is the basis and foundation of all agricultural wealth.

The same remark applies to navigation. Thousands of vessels will proceed to the whale fishery; and, in a short time, we shall possess a navy capable of maintaining the honor of France, and gratifying the patriotic aspirations of your petitioners, the undersigned candle-makers and others.

Only have the goodness to reflect, Gentlemen, and you will be convinced that there is, perhaps, no Frenchman, from the wealthy coalmaster to the humblest vender of lucifer matches, whose lot will not be ameliorated by the success of this our petition.

SUMMARY

LO40.1 List and discuss several key facts about international trade.

The United States leads the world in the combined volume of exports and imports. Other major trading nations are Germany, Japan, the western European nations, and the Asian economies of China, South Korea, Taiwan, and Singapore. The United States' principal exports include chemicals, agricultural products, consumer durables, semiconductors, and aircraft; principal imports include petroleum, automobiles, metals, household appliances, and computers.

LO40.2 Define comparative advantage and demonstrate how specialization and trade add to a nation's output.

World trade is based on three considerations: the uneven distribution of economic resources among nations, the fact that efficient production of various goods requires particular techniques or combinations of resources, and the differentiated products produced among nations.

Mutually advantageous specialization and trade are possible between any two nations if they have different domestic opportunity-cost ratios for any two products. By specializing on the basis of comparative advantage, nations can obtain larger real incomes with fixed amounts of resources. The terms of trade determine how this increase in world output is shared by the trading nations. Increasing (rather than constant) opportunity costs limit specialization and trade.

LO40.3 Describe how differences between world prices and domestic prices prompt exports and imports.

A nation's export supply curve shows the quantities of a product the nation will export at world prices that exceed the domestic price (the price in a closed, no-international-trade economy). A nation's import demand curve reveals the quantities of a product it will import at world prices below the domestic price.

In a two-nation model, the equilibrium world price and the equilibrium quantities of exports and imports occur where one nation's export supply curve intersects the other nation's import demand curve. A nation will export a particular product if the world price exceeds the domestic price; it will import the product if the world price is less than the domestic price. The country with the lower costs of production will be the exporter and the country with the higher costs of production will be the importer.

LO40.4 Analyze the economic effects of tariffs and quotas.

Trade barriers take the form of protective tariffs, quotas, nontariff barriers, and "voluntary" export restrictions. Export subsidies also distort international trade. Supply and demand analysis demonstrates that protective tariffs and quotas increase the prices and reduce the quantities demanded of the affected goods. Sales by foreign exporters diminish; domestic producers, however, gain higher prices and enlarged sales. Consumer losses from trade restrictions greatly exceed producer and government gains, creating an efficiency loss to society.

LO40.5 Analyze the validity of the most frequently presented arguments for protectionism.

The strongest arguments for protection are the infant industry and military self-sufficiency arguments. Most other arguments for protection are interest-group appeals or reasoning fallacies that emphasize producer interests over consumer interests or stress the immediate effects of trade barriers while ignoring long-run consequences.

The cheap foreign labor argument for protection fails because it focuses on labor costs per hour rather than on what really matters, labor costs per unit of output. Due to higher productivity, firms in high-wage countries like the United States can have lower wage costs per unit of output than competitors in low-wage countries. Whether they do will depend on how their particular wage and productivity levels compare with those of their competitors in low-wage countries.

LO40.6 Identify and explain the objectives of GATT, WTO, EU, eurozone, and NAFTA and discuss offshoring and trade adjustment assistance.

In 1947 the General Agreement on Tariffs and Trade (GATT) was formed to encourage nondiscriminatory treatment for all member nations, to reduce tariffs, and to eliminate import quotas. The Uruguay Round of GATT negotiations (1993) reduced tariffs and quotas, liberalized trade in services, reduced agricultural subsidies, reduced pirating of intellectual property, and phased out quotas on textiles.

GATT's successor, the World Trade Organization (WTO), had 161 member nations in 2015. It implements WTO agreements, rules on trade disputes between members, and provides forums for continued discussions on trade liberalization. The latest round of trade negotiations—the Doha Development Agenda—began in late 2001 and as of 2016 was still in progress.

Free-trade zones liberalize trade within regions. Two examples of free-trade arrangements are the 28-member European Union (EU) and the North American Free Trade Agreement (NAFTA), comprising Canada, Mexico, and the United States. Nineteen EU nations have abandoned their national currencies for a common currency called the euro.

The Trade Adjustment Assistance Act of 2002 recognizes that trade liberalization and increased international trade can create job loss for many workers. The Act therefore provides cash assistance, education and training benefits, health care subsidies, and wage subsidies (for persons aged 50 or older) to qualified workers displaced by imports or relocations of plants from the United States to abroad.

Offshoring is the practice of shifting work previously done by Americans in the United States to workers located in other nations. Although offshoring reduces some U.S. jobs, it lowers production costs, expands sales, and therefore may create other U.S. jobs. Less than 4 percent of all job losses in the United States each year are caused by imports, offshoring, and plant relocation abroad.

- Suppose that the opportunity-cost ratio for watches and cheese is $1C \equiv 1W$ in Switzerland but $1C \equiv 4W$ in Japan. At which of the following international exchange ratios (terms of trade) will Switzerland and Japan be willing to specialize and engage in trade with each other? **LO40.2**
Select one or more answers from the choices shown.
 - $1C \equiv 3W$.
 - $1C \equiv \frac{1}{2}W$.
 - $1C \equiv 5W$.
 - $\frac{1}{2}C \equiv 1W$.
 - $2C \equiv 1W$.
- We see quite a bit of international trade in the real world. And trade is driven by specialization. So why don't we see full specialization—for instance, all cars in the world being made in South Korea, or all the mobile phones in the world being made in China? Choose the best answer from among the following choices. **LO40.2**
 - High tariffs.
 - Extensive import quotas.
 - Increasing opportunity costs.
 - Increasing returns.
- Which of the following are benefits of international trade? **LO40.2**
Choose one or more answers from the choices shown.
 - A more efficient allocation of resources.
 - A higher level of material well-being.
 - Gains from specialization.
 - Promoting competition.
 - Deterring monopoly.
 - Reducing the threat of war.
- True or False: If a country is open to international trade, the domestic price can differ from the international price. **LO40.3**
- Suppose that the current international price of wheat is \$6 per bushel and that the United States is currently exporting 30 million bushels per year. If the United States suddenly became a closed economy with respect to wheat, would the domestic price of wheat in the United States end up higher or lower than \$6? **LO40.3**
 - Higher.
 - Lower.
 - The same.
- Suppose that if Iceland and Japan were both closed economies, the domestic price of fish would be \$100 per ton in Iceland and \$90 per ton in Japan. If the two countries decided to open up to international trade with each other, which of the following could be the equilibrium international price of fish once they begin trading? **LO40.3**
 - \$75.
 - \$85.
 - \$95.
 - \$105.
- Draw a domestic supply-and-demand diagram for a product in which the United States does not have a comparative advantage. What impact do foreign imports have on domestic price and quantity? On your diagram show a protective tariff that eliminates approximately one-half of the assumed imports. What are the price-quantity effects of this tariff on (a) domestic consumers, (b) domestic producers, and (c) foreign exporters? How would the effects of a quota that creates the same amount of imports differ? **LO40.4**
- American apparel makers complain to Congress about competition from China. Congress decides to impose either a tariff or a quota on apparel imports from China. Which policy would Chinese apparel manufacturers prefer? **LO40.4**
 - Tariff.
 - Quota.

PROBLEMS

- Assume that the comparative-cost ratios of two products—baby formula and tuna fish—are as follows in the nations of Canswicki and Tunata:
 Canswicki: 1 can baby formula \equiv 2 cans tuna fish
 Tunata: 1 can baby formula \equiv 4 cans tuna fish

In what product should each nation specialize? Which of the following terms of trade would be acceptable to both nations: (a) 1 can baby formula \equiv $2\frac{1}{2}$ cans tuna fish; (b) 1 can baby formula \equiv 1 can tuna fish; (c) 1 can baby formula \equiv 5 cans tuna fish? **LO40.2**

2. The accompanying hypothetical production possibilities tables are for New Zealand and Spain. Each country can produce apples and plums. Plot the production possibilities data for each of the two countries separately. Referring to your graphs, answer the following: **LO40.2**

New Zealand's Production Possibilities Table
(Millions of Bushels)

Product	Production Alternatives			
	A	B	C	D
Apples	0	20	40	60
Plums	15	10	5	0

Spain's Production Possibilities Table

Apples	0	20	40	60
Plums	60	40	20	0

- What is each country's cost ratio of producing plums and apples?
- Which nation should specialize in which product?
- Show the trading possibilities lines for each nation if the actual terms of trade are 1 plum for 2 apples. (Plot these lines on your graph.)
- Suppose the optimum product mixes before specialization and trade were alternative B in New Zealand and alternative S in Spain. What would be the gains from specialization and trade?

3. The following hypothetical production possibilities tables are for China and the United States. Assume that before specialization and trade, the optimal product mix for China is alternative B and for the United States is alternative U. **LO40.2**
- Are comparative-cost conditions such that the two areas should specialize? If so, what product should each produce?
 - What is the total gain in apparel and chemical output that would result from such specialization?
 - What are the limits of the terms of trade? Suppose that the actual terms of trade are 1 unit of apparel for 1 unit of chemicals and that 4 units of apparel are exchanged for 6 units of chemicals. What are the gains from specialization and trade for each nation?

If you take a U.S. dollar to the bank and ask to exchange it for U.S. currency, you will get a puzzled look. If you persist, you may get a dollar's worth of change: One U.S. dollar can buy exactly one U.S. dollar. But on April 5, 2016, for example, 1 U.S. dollar could buy 3,087 Colombian pesos, 1.32 Australian dollars, 0.71 British pound, 1.31 Canadian dollars, 0.88 European euro, 110.48 Japanese yen, or 17.64 Mexican pesos. What explains this seemingly haphazard array of exchange rates?

In Chapter 40 we examined comparative advantage as the underlying economic basis of world trade and discussed the effects of barriers to free trade. Now we introduce the highly important monetary and financial aspects of international trade.

International Financial Transactions

LO41.1 Explain how currencies of different nations are exchanged when international transactions take place.

This chapter focuses on international financial transactions, the vast majority of which fall into two broad categories: international trade and international asset transactions. International trade involves either purchasing or selling currently produced goods or services across an international border.

Examples include an Egyptian firm exporting cotton to the United States and an American company hiring an Indian call center to answer its phones. International asset transactions involve the transfer of the property rights to either real or financial assets between the citizens of one country and the citizens of another country. International asset transactions include activities like buying foreign stocks or selling your house to a foreigner.

These two categories of international financial transactions reflect the fact that whether they live in different countries or the same country, individuals and firms can only exchange two things with each other: currently produced goods and services or assets. With regard to assets, however, money is by far the most commonly exchanged asset. Only rarely will you encounter a barter situation in which people directly exchange one nonmoney asset for another nonmoney asset—such as trading a car for 500 shares of Microsoft stock or a cow for 30 chickens and a tank of diesel fuel.

As a result, there are two basic types of transactions:

- People trading either goods or services for money.
- People trading assets for money.

In either case, money flows from the buyers of the goods, services, or assets to the sellers of the goods, services, or assets. In the context of international trade, importers are buyers and exporters are sellers. As a result, *imports cause outflows of money while exports cause inflows of money.*

When the buyers and sellers are both from places that use the same currency, there is no confusion about what type of money to use. Americans from California and Wisconsin will use their common currency, the dollar. People from France and Germany will use their common currency, the euro. However, when the buyers and sellers are from places that use different currencies, intermediate asset transactions have to take place: The buyers must convert their own currencies into the currencies that the sellers use and accept.

As an example, consider the case of an English software company that wants to buy a supercomputer made by an American company. The American company sells these high-powered machines for \$300,000. To pay for the machine, the English company has to convert some of the money it has (British pounds) into the money that the American company will accept (U.S. dollars). This process is not difficult. As we will soon explain in detail, there are many easy-to-use foreign exchange markets in which those who wish to sell pounds and buy dollars can interact with others who wish to sell dollars and buy pounds. The demand and supply created by these two groups determine the equilibrium exchange rate, which, in turn, determines how many pounds our English company will have to convert to pay for the supercomputer. For instance, if the exchange rate is £1 = \$2, then the English company will have to convert £150,000 to obtain the \$300,000 necessary to purchase the computer.

QUICK REVIEW 41.1

- ✓ International financial transactions involve trade either in currently produced goods and services or in assets.
- ✓ While imports cause outflows of money, exports of goods, services, and assets create inflows of money.
- ✓ If buyers and sellers use different currencies, then foreign exchange transactions take place so that the exporter can be paid in his or her own currency.

The Balance of Payments

L041.2 Analyze the balance sheet the United States uses to account for the international payments it makes and receives.

A nation's **balance of payments** is the sum of all the financial transactions that take place between its residents and the residents of foreign nations. Most of these transactions fall into the two main categories that we have just discussed: international trade and international asset transactions. As a result, nearly all the items included in the balance of payments are things such as exports and imports of goods, exports and imports of services, and international purchases and sales of financial and real assets. But the balance of payments also includes international transactions that fall outside of these main categories—things such as tourist expenditures, interest and dividends received or paid abroad, debt forgiveness, and remittances made by immigrants to their relatives back home.

The Bureau of Economic Analysis at the U.S. Department of Commerce compiles a balance-of-payments statement each year. This statement summarizes all of the millions of payments that individuals and firms in the United States receive from foreigners as well as all of the millions of payments that individuals and firms in the United States make to foreigners. It shows “flows” of inpayments of money *to* the United States and outpayments of money *from* the United States. For convenience, all of these money payments are given in terms of dollars. This is true despite the fact that some of them actually may have been made using foreign currencies—as when, for instance, an American company converts dollars into euros to buy something from an Italian company. When including this outpayment of money from the United States, the accountants who compile the balance-of-payments statement use the number of dollars the American company converted—rather than the number of euros that were actually used to make the purchase.

Table 41.1 is a simplified balance-of-payments statement for the United States in 2015. Because most international financial transactions fall into only two categories—international trade and international asset transactions—the balance-of-payments statement is organized into two broad

categories. *The current account* located at the top of the table primarily treats international trade. *The capital and financial account* at the bottom of the table primarily treats international asset transactions.

Current Account

The top portion of Table 41.1 that mainly summarizes U.S. trade in currently produced goods and services is called the **current account**. Items 1 and 2 show U.S. exports and imports of goods (merchandise) in 2015. U.S. exports have a *plus* (+) sign because they are a *credit*; they generate flows of money toward the United States. U.S. imports have a *minus* (−) sign because they are a *debit*; they cause flows of money out of the United States.

Balance on Goods Items 1 and 2 in Table 41.1 reveal that in 2015 U.S. goods exports of \$1,513 billion were less than U.S. goods imports of \$2,273 billion. A country’s *balance of trade on goods* is the difference between its exports and its imports of goods. If exports exceed imports, the result is a surplus on the balance of goods. If imports exceed exports, there is a trade deficit on the balance of goods. We note in item 3 that, in 2015, the United States incurred a trade deficit on goods of \$760 billion.

Balance on Services The United States exports not only goods, such as airplanes and computer software, but also services, such as insurance, consulting, travel, and investment advice, to residents of foreign nations. Item 4 in Table 41.1 shows that these service “exports” totaled \$710 billion in 2015. Since they generate flows of money toward the United States, they are a credit (thus the + sign). Item 5 indicates that the United States “imports” similar services from foreigners. Those service imports were \$491 billion in 2015, and since they generate flows of money out of the United States, they are a debit (thus the − sign). Summed together, items 4 and 5 indicate that the balance on services (item 6) in 2015 was \$219 billion. The **balance on goods and services** shown as item 7 is the difference between U.S. exports of goods and services (items 1 and 4) and U.S. imports of goods and services (items 2 and 5). In 2015, U.S. imports of goods and services exceeded U.S. exports of goods and services by \$541 billion. So a **trade deficit** of that amount occurred. In contrast, a **trade surplus** occurs when exports of goods and services exceed imports of goods and services. (Global Perspective 41.1 shows U.S. trade deficits and surpluses with selected nations.)

Balance on Current Account Items 8 and 9 are not items relating directly to international trade in goods and

services. But they are listed as part of the current account (which is mostly about international trade in goods and services) because they are international financial flows that in some sense compensate for things that can be conceptualized as being *like* international trade in either goods or services. For instance, item 8, *net investment income*, represents the difference between (1) the interest and dividend payments foreigners paid U.S. citizens and companies for the services provided by U.S. capital invested abroad (“exported” capital) and (2) the interest and dividends the U.S. citizens and companies paid for the services provided by foreign capital invested here (“imported” capital). Observe that in 2015 U.S. net investment income was a positive \$191 billion.

Item 9 shows net transfers, both public and private, between the United States and the rest of the world. Included here is foreign aid, pensions paid to U.S. citizens living abroad, and remittances by immigrants to relatives abroad. These \$136 billion of transfers are net U.S. outpayments (and therefore listed as a negative number in Table 41.1). They are listed as part of the current account because they can be thought of as the financial flows that accompany the exporting of goodwill and the importing of “thank you notes.”

By adding all transactions in the current account, we obtain the **balance on current account** shown in item 10. In 2015 the United States had a current account deficit of

\$486 billion. This means that the U.S. current account transactions created outpayments from the United States greater than inpayments to the United States.

Capital and Financial Account

The bottom portion of the current account statement summarizes U.S. international asset transactions. It is called the **capital and financial account** and consists of two separate accounts: the *capital account* and the *financial account*.

Capital Account The capital account mainly measures debt forgiveness—which is an asset transaction because the person forgiving a debt essentially hands the IOU back to the borrower. It is a “net” account (one that can be either + or –). The \$0 billion listed in line 11 tells us that in 2015 foreigners forgave exactly as much debt owed to them by Americans as Americans forgave debt owed to them by foreigners. Any positive (+) entry in line 11 would indicate a credit; positive amounts are an “on-paper” inpayment (asset transfer) by the net amount of debt forgiven.

Financial Account The financial account summarizes international asset transactions having to do with international purchases and sales of real or financial assets. Line 12 lists the amount of foreign purchases of assets in the United States. It has a + sign because any purchase of an American-owned asset by a foreigner generates a flow of money toward the American who sells the asset. Line 13 lists U.S. purchases of assets abroad. These have a – sign because such purchases generate a flow of money from the Americans who buy foreign assets toward the foreigners who sell them those assets.

Items 12 and 13 added together yield a \$486 billion balance on the financial account for 2015 (line 14). In 2015 the United States “exported” \$589 billion of ownership of its real and financial assets and “imported” \$103 billion. Thought of differently, this surplus in the financial account brought in income of \$486 billion to the United States. The **balance on capital and financial account** (line 15) is also \$486 billion. It is the sum of the \$0 billion credit on the capital account and the \$486 billion surplus on the financial account. Observe that this \$486 billion surplus in the capital and financial account equals the \$486 billion deficit in the current account. This is not an accident. The two numbers always equal—or “balance.” That’s why the statement is called the *balance* of payments. It has to balance. Let’s see why.

Why the Balance?

The balance on the current account and the balance on the capital and financial account must always sum to zero because any deficit or surplus in the current account automatically

creates an offsetting entry in the capital and financial account. People can only trade one of two things with each other: currently produced goods and services or preexisting assets. Therefore, if trading partners have an imbalance in their trade of currently produced goods and services, the only way to make up for that imbalance is with a net transfer of assets from one party to the other.

To see why this is true, suppose that John (an American) makes shoes and Henri (a Swiss citizen) makes watches and that the pair only trade with each other. Assume that their financial assets consist entirely of money, with each beginning the year with \$1,000 in his bank account. Suppose that this year John exports \$300 of shoes to Henri and imports \$500 of watches from Henri. John therefore ends the year with a \$200 goods deficit with Henri.

John and Henri's goods transactions, however, also result in asset exchanges that cause a net transfer of assets from John to Henri equal in size to John's \$200 goods deficit with Henri. This is true because Henri pays John \$300 for his shoes while John pays Henri \$500 for his watches. The *net* result of these opposite-direction asset movements is that \$200 of John's initial assets of \$1,000 are transferred to Henri. This is unavoidable because the \$300 John receives from his exports pays for only the first \$300 of his \$500 of imports. The only way for John to pay for the remaining \$200 of imports is for him to transfer \$200 of his initial asset holdings to Henri. Consequently, John's assets decline by \$200 from \$1,000 to \$800, and Henri's assets rise from \$1,000 to \$1,200.

Consider how the transaction between John and Henri affects the U.S. balance-of-payments statement (Table 41.1), other things equal. John's \$200 goods deficit with Henri shows up in the U.S. current account as a $-\$200$ entry in the balance on goods account (line 3) and carries down to a $-\$200$ entry in the balance on current account (line 10).

In the capital and financial account, this \$200 is recorded as $+\$200$ in the account labeled foreign purchases of assets in the United States (line 12). This $+\$200$ then carries down to the balance on capital and financial account (line 15). Think of it this way: Henri has in essence used \$200 worth of watches to purchase \$200 of John's initial \$1,000 holding of assets. The $+\$200$ entry in line 12 (foreign purchases of assets in the United States) simply recognizes this fact. This $+\$200$ exactly offsets the $-\$200$ in the current account.

Thus, the balance of payments always balances. Any current account deficit or surplus in the top half of the statement automatically generates an offsetting international asset transfer that shows up in the capital and financial account in the bottom half of the statement. More specifically, current account deficits simultaneously generate transfers of assets to foreigners, while current account surpluses automatically generate transfers of assets from foreigners.

QUICK REVIEW 41.2

- ✓ A nation's balance-of-payments statement summarizes all of the international financial transactions that take place between its residents and the residents of all foreign nations. It includes the current account balance and the capital and financial account balance.
- ✓ The current account balance is a nation's exports of goods and services less its imports of goods and services plus its net investment income and net transfers.
- ✓ The capital and financial account balance includes the net amount of the nation's debt forgiveness as well as the nation's sale of real and financial assets to people living abroad less its purchases of real and financial assets from foreigners.
- ✓ The current account balance and the capital and financial account balance always sum to zero because any current account imbalance automatically generates an offsetting international asset transfer.

Flexible Exchange Rates

L041.3 Discuss how exchange rates are determined in currency markets that have flexible exchange rates.

There are two pure types of exchange-rate systems:

- A **flexible- or floating-exchange-rate system** through which demand and supply determine exchange rates and in which no government intervention occurs.
- A **fixed-exchange-rate system** through which governments determine exchange rates and make necessary adjustments in their economies to maintain those rates.

We begin by looking at flexible exchange rates. Let's examine the rate, or price, at which U.S. dollars might be exchanged for British pounds in the market for foreign currency. In **Figure 41.1 (Key Graph)** we show demand D_1 and supply S_1 of pounds. Note that both the demand and supply of pounds are expressed in terms of U.S. dollars. They interact to determine the equilibrium price for pounds—which is expressed in terms of how many dollars are required to purchase one pound.

The *demand-for-pounds curve* D_1 is downsloping because all British goods and services will be cheaper to Americans if pounds become less expensive. That is, at lower dollar prices for pounds, Americans can obtain more pounds and therefore more British goods and services per dollar. To buy those cheaper British goods, U.S. consumers will increase the quantity of pounds they demand.

As a concrete example, suppose that you are a U.S. citizen on vacation in London. If it only takes 50 cents to buy 1 pound,

FIGURE 41.1 The market for foreign currency (pounds). The intersection of the demand-for-pounds curve D_1 and the supply-of-pounds curve S_1 determines the equilibrium dollar price of pounds, here, \$2. That means that the exchange rate is $\$2 = \pounds 1$. Not shown: An increase in demand for pounds or a decrease in supply of pounds will increase the dollar price of pounds and thus cause the pound to appreciate. Also not shown: A decrease in demand for pounds or an increase in the supply of pounds will reduce the dollar price of pounds, meaning that the pound has depreciated.

QUICK QUIZ FOR FIGURE 41.1

- Which of the following statements is true?
 - The quantity of pounds demanded falls when the dollar appreciates.
 - The quantity of pounds supplied declines as the dollar price of the pound rises.
 - At the equilibrium exchange rate, the pound price of \$1 is $\pounds \frac{1}{2}$.
 - The dollar appreciates if the demand for pounds increases.
- At the price of \$2 for £1 in this figure:
 - the dollar-pound exchange rate is unstable.
 - the quantity of pounds supplied equals the quantity demanded.
 - the dollar price of £1 equals the pound price of \$1.
 - U.S. goods exports to Britain must equal U.S. goods imports from Britain.
- Other things equal, a leftward shift of the demand curve in this figure:
 - would depreciate the dollar.
 - would create a shortage of pounds at the previous price of \$2 for £1.
 - might be caused by a major recession in the United States.
 - might be caused by a significant rise of real interest rates in Britain.
- Other things equal, a rightward shift of the supply curve in this figure would:
 - depreciate the dollar and might be caused by a significant rise of real interest rates in Britain.
 - depreciate the dollar and might be caused by a significant fall of real interest rates in Britain.
 - appreciate the dollar and might be caused by a significant rise of real interest rates in the United States.
 - appreciate the dollar and might be caused by a significant fall of real interest rates in the United States.

Answers: 1. c; 2. b; 3. c; 4. c

you will end up wanting to buy a lot more souvenirs to take home than if it takes \$1.50 to buy 1 pound. The lower the dollar price of purchasing a pound, the less expensive British goods and services will appear to you and the more dollars you will want to sell for pounds in order to get “cheap” British products. So the demand curve for pounds slopes downward.

The *supply-of-pounds curve* S_1 is upsloping because the British will purchase more U.S. goods when the dollar price of pounds rises (that is, as the pound price of dollars falls). When the British buy more U.S. goods, they supply a greater quantity of pounds to the foreign exchange market. In other words, they must exchange pounds for dollars to purchase U.S. goods. So, when the dollar price of pounds rises, the quantity of pounds supplied goes up.

As a concrete example, suppose that a Facebook friend from London wants to buy Google stock. Because Google is a U.S. company, he will need dollars to buy Google shares. If he can convert 1 pound into \$3, he will want to buy a lot more shares of Google than if each pound only converts into \$1.75. The more dollars he can get from selling a pound, the less expensive Google stock will appear to him and the more pounds he will want to sell in order to get “cheap” Google stock. So the supply curve for pounds slopes upward.

The intersection of the supply curve and the demand curve will determine the dollar price of pounds. Here, that price (exchange rate) is \$2 for £1. At this exchange rate, the quantities of pounds supplied and demanded are equal; neither a shortage nor a surplus of pounds occurs.

Depreciation and Appreciation

An exchange rate determined by market forces can, and often does, change daily like stock and bond prices. When the dollar price of pounds *rises*, for example, from $\$2 = \pounds 1$ to $\$3 = \pounds 1$, the dollar has *depreciated* relative to the pound (and the pound has appreciated relative to the dollar). When a currency depreciates, more units of it (dollars) are needed to buy a single unit of some other currency (a pound).

When the dollar price of pounds *falls*, for example, from $\$2 = \pounds 1$ to $\$1 = \pounds 1$, the dollar has *appreciated* relative to the pound. When a currency appreciates, fewer units of it (dollars) are needed to buy a single unit of some other currency (pounds).

In our U.S.-Britain example, depreciation of the dollar means an appreciation of the pound, and vice versa. When the dollar price of a pound jumps from $\$2 = \pounds 1$ to $\$3 = \pounds 1$, the pound has appreciated relative to the dollar because it takes fewer pounds to buy \$1. At $\$2 = \pounds 1$, it took $\pounds \frac{1}{2}$ to buy \$1; at $\$3 = \pounds 1$, it takes only $\pounds \frac{1}{3}$ to buy \$1. Conversely, when the dollar appreciated relative to the pound, the pound depreciated relative to the dollar. More pounds were needed to buy a dollar.

In general, the relevant terminology and relationships between the U.S. dollar and another currency are as follows (where the “ \equiv ” sign means “is equivalent to”).

- Dollar price of foreign currency increases \equiv dollar depreciates relative to the foreign currency \equiv foreign currency price of dollar decreases \equiv foreign currency appreciates relative to the dollar.
- Dollar price of foreign currency decreases \equiv dollar appreciates relative to the foreign currency \equiv foreign currency price of dollar increases \equiv foreign currency depreciates relative to the dollar.

Determinants of Flexible Exchange Rates

What factors would cause a nation’s currency to appreciate or depreciate in the market for foreign exchange? Here are three generalizations:

- If the demand for a nation’s currency increases (other things equal), that currency will appreciate; if the demand declines, that currency will depreciate.
- If the supply of a nation’s currency increases, that currency will depreciate; if the supply decreases, that currency will appreciate.
- If a nation’s currency appreciates, some foreign currency depreciates relative to it.

With these generalizations in mind, let’s examine the determinants of exchange rates—the factors that shift the demand or supply curve for a certain currency. As we do so, keep in mind that the other-things-equal assumption is always in force. Also note that we are discussing factors *that change the*

exchange rate, not things that change *as a result of* a change in the exchange rate.

Changes in Tastes Any change in consumer tastes or preferences for the products of a foreign country may alter the demand for that nation’s currency and change its exchange rate. If technological advances in U.S. wireless phones make them more attractive to British consumers and businesses, then the British will supply more pounds in the exchange market to purchase more U.S. wireless phones. The supply-of-pounds curve will shift to the right, causing the pound to depreciate and the dollar to appreciate.

In contrast, the U.S. demand-for-pounds curve will shift to the right if British woolen apparel becomes more fashionable in the United States. So the pound will appreciate and the dollar will depreciate.

Relative Income Changes A nation’s currency is likely to depreciate if its growth of national income is more rapid than that of other countries. Here’s why: A country’s imports vary directly with its income level. As national income rises in the United States, Americans will buy both more domestic goods and more foreign goods. If the U.S. economy is expanding rapidly and the British economy is stagnant, U.S. imports of British goods, and therefore U.S. demands for pounds, will increase. The dollar price of pounds will rise, so the dollar will depreciate.

Relative Inflation Rate Changes Other things equal, changes in the relative rates of inflation of two nations change their relative price levels and alter the exchange rate between their currencies. The currency of the nation with the higher inflation rate—the more rapidly rising price level—tends to depreciate. Suppose, for example, that inflation is zero percent in Great Britain and 5 percent in the United States so that prices, on average, are rising by 5 percent per year in the United States while, on average, remaining unchanged in Great Britain. U.S. consumers will seek out more of the now relatively lower-priced British goods, increasing the demand for pounds. British consumers will purchase less of the now relatively higher-priced U.S. goods, reducing the supply of pounds. This combination of increased demand for pounds and reduced supply of pounds will cause the pound to appreciate and the dollar to depreciate.

According to the **purchasing-power-parity theory**, exchange rates should eventually adjust such that they equate the purchasing power of various currencies. If a certain market basket of identical products costs \$10,000 in the United States and £5,000 in Great Britain, the exchange rate should move to $\$2 = \pounds 1$. That way, a dollar spent in the United States will buy exactly as much output as it would if it were first converted to pounds (at the $\$2 = \pounds 1$ exchange rate) and used to buy output in Great Britain.

In terms of our example, 5 percent inflation in the United States will increase the price of the market basket from \$10,000 to \$10,500, while the zero percent inflation in Great Britain will leave the market basket priced at £5,000. For purchasing power parity to hold, the exchange rate would have to move from $\$2 = \pounds 1$ to $\$2.10 = \pounds 1$. That means the dollar therefore would depreciate and the pound would appreciate. In practice, however, not all exchange rates move precisely to equate the purchasing power of various currencies and thereby achieve “purchasing power parity,” even over long periods.

Relative Interest Rates Changes in relative interest rates between two countries may alter their exchange rate. Suppose that real interest rates rise in the United States but stay constant in Great Britain. British citizens will then find the United States a more attractive place in which to loan money directly or loan money indirectly by buying bonds. To make these loans, they will have to supply pounds in the foreign exchange market to obtain dollars. The increase in the supply of pounds results in depreciation of the pound and appreciation of the dollar.

Changes in Relative Expected Returns on Stocks, Real Estate, and Production Facilities International investing extends beyond buying foreign bonds. It includes international investments in stocks and real estate as well as foreign purchases of factories and production facilities. Other things equal, the extent of this foreign investment depends on relative expected returns. To make the investments, investors in one country must sell their currencies to purchase the foreign currencies needed for the foreign investments.

For instance, suppose that investing in England suddenly becomes more popular due to a more positive outlook

regarding expected returns on stocks, real estate, and production facilities there. U.S. investors therefore will sell U.S. assets to buy more assets in England. The U.S. assets will be sold for dollars, which will then be brought to the foreign exchange market and exchanged for pounds, which will in turn be used to purchase British assets. The increased demand for pounds in the foreign exchange market will cause the pound to appreciate and therefore the dollar to depreciate relative to the pound.

Speculation Currency speculators are people who buy and sell currencies with an eye toward reselling or repurchasing them at a profit. Suppose speculators expect the U.S. economy to (1) grow more rapidly than the British economy and (2) experience more rapid inflation than Britain. These expectations translate into an anticipation that the pound will appreciate and the dollar will depreciate. Speculators who are holding dollars will therefore try to convert them into pounds. This effort will increase the demand for pounds and cause the dollar price of pounds to rise (that is, cause the dollar to depreciate). A self-fulfilling prophecy occurs: The pound appreciates and the dollar depreciates because speculators act on the belief that these changes will in fact take place. In this way, speculation can cause changes in exchange rates.

Table 41.2 has more illustrations of the determinants of exchange rates; the table is worth careful study.

Disadvantages of Flexible Exchange Rates

Flexible exchange rates may cause several significant problems. These are all related to the fact that flexible exchange rates are often volatile and can change by a large amount in

TABLE 41.2 Determinants of Exchange Rates: Factors That Change the Demand for or the Supply of a Particular Currency and Thus Alter the Exchange Rate

Determinant	Examples
Change in tastes	Japanese electronic equipment declines in popularity in the United States (Japanese yen depreciates; U.S. dollar appreciates). European tourists reduce visits to the United States (U.S. dollar depreciates; European euro appreciates).
Change in relative incomes	England encounters a recession, reducing its imports, while U.S. real output and real income surge, increasing U.S. imports (British pound appreciates; U.S. dollar depreciates).
Change in relative inflation rates	Switzerland experiences a 3% inflation rate compared to Canada's 10% rate (Swiss franc appreciates; Canadian dollar depreciates).
Change in relative real interest rates	The Federal Reserve drives up interest rates in the United States, while the Bank of England takes no such action (U.S. dollar appreciates; British pound depreciates).
Changes in relative expected returns on stocks, real estate, or production facilities	Corporate tax cuts in the United States raise expected after-tax investment returns in the United States relative to those in Europe (U.S. dollar appreciates; the euro depreciates).
Speculation	Currency traders believe South Korea will have much greater inflation than Taiwan (South Korean won depreciates; Taiwanese dollar appreciates). Currency traders think Norway's interest rates will plummet relative to Denmark's rates (Norway's krone depreciates; Denmark's krone appreciates).

FIGURE 41.2 The dollar-pound exchange rate, 1970–2015. Before January 1971, the dollar-pound exchange rate was fixed at \$2.40 = £1. Since that time, its value has been determined almost entirely by market forces, with only occasional government interventions. Under these mostly flexible conditions, the dollar-pound exchange rate has varied considerably. For instance, in 1981 it took \$2.02 to buy a pound, but by 1985 only \$1.50 was needed to buy a pound. In contrast, between 2001 and 2007 the dollar price of a pound rose from \$1.44 to \$2.00, indicating that the dollar had depreciated relative to the pound. The dollar then sank back to \$1.57 per British pound in 2009 and remained at about that level through 2015.

just a few weeks or months. In addition, they often take substantial swings that can last several years or more. This can be seen in Figure 41.2, which plots the dollar-pound exchange rate from 1970 through 2016. [You can track other exchange rates, for example, the dollar-euro or dollar-yen rate, by going to the Federal Reserve website, www.federalreserve.gov, selecting Economic Research & Data, then Data Releases, and then clicking on “Foreign Exchange Rates (H.10/G.5)” under the heading that reads Exchange Rates and International Data.]

Uncertainty and Diminished Trade The risks and uncertainties associated with flexible exchange rates may discourage the flow of trade. Suppose a U.S. automobile dealer contracts to purchase 10 British cars for £150,000. At the current exchange rate of, say, \$2 for £1, the U.S. importer expects to pay \$300,000 for these automobiles. But if during the 3-month delivery period the rate of exchange shifts to \$3 for £1, the £150,000 payment contracted by the U.S. importer will be \$450,000.

That increase in the dollar price of pounds may thus turn the U.S. importer’s anticipated profit into a substantial loss. Aware of the possibility of an adverse change in the exchange rate, the U.S. importer may not be willing to assume the risks involved. The U.S. firm may confine its operations to domestic automobiles, so international trade in this product will not occur.

The same thing can happen with investments. Assume that when the exchange rate is \$3 to £1, a U.S. firm invests \$30,000 (or £10,000) in a British enterprise. It estimates a return of 10 percent; that is, it anticipates annual earnings of

\$3,000 or £1,000. Suppose these expectations prove correct in that the British firm earns £1,000 in the first year on the £10,000 investment. But suppose that during the year, the value of the dollar appreciates to \$2 = £1. The absolute return is now only \$2,000 (rather than \$3,000), and the rate of return falls from the anticipated 10 percent to only $6\frac{2}{3}$ percent (= \$2,000/\$30,000). Investment is risky in any case. The added risk of changing exchange rates may persuade the U.S. investor not to venture overseas.

Terms-of-Trade Changes A decline in the international value of its currency will worsen a nation’s terms of trade. For example, an increase in the dollar price of a pound will mean that the United States must export more goods and services to finance a specific level of imports from Britain.

Instability Flexible exchange rates may destabilize the domestic economy because wide fluctuations stimulate and then depress industries producing exported goods. If the U.S. economy is operating at full employment and its currency depreciates, the results will be inflationary, for two reasons. (1) Foreign demand for U.S. goods may rise, increasing total spending and pulling up U.S. prices. Also, the prices of all U.S. imports will increase. (2) Conversely, appreciation of the dollar will lower U.S. exports and increase imports, possibly causing unemployment.

Flexible or floating exchange rates also may complicate the use of domestic stabilization policies in seeking full employment and price stability. This is especially true for nations whose exports and imports are large relative to their total domestic output.

QUICK REVIEW 41.3

- ✓ Under a flexible exchange rate system, exchange rates are determined by the demand for, and supply of, individual national currencies in the foreign exchange market.
- ✓ Determinants of flexible exchange rates (factors that shift currency supply and demand curves) include (a) changes in tastes; (b) relative national incomes; (c) relative inflation rates; (d) real interest rates; (e) relative expected returns on stocks, real estate, and production facilities; and (f) speculation.
- ✓ The volatility of flexible exchange rates may have several negative consequences, including discouraging international trade, worsening a nation's terms of trade, and destabilizing a nation's domestic economy by depressing export industries.

Fixed Exchange Rates

LO41.4 Describe the differences between flexible and fixed exchange rates, including how changes in foreign exchange reserves bring about automatic changes in the domestic money supply under a fixed exchange rate.

To circumvent the disadvantages of flexible exchange rates, governments have at times fixed or “pegged” their exchange rates. Under a fixed exchange rate, the government stands ready to buy and sell as much currency as is demanded or supplied at the constant (fixed) exchange rate that it announces.

To see how this works, suppose that the U.S. government decides to fix the dollar-pound exchange rate at $\$2 = \pounds 1$. To enforce that peg, the U.S. government must stand ready to exchange both pounds for dollars as well as dollars for pounds at the fixed ratio of $\$2 = \pounds 1$. If Americans want to exchange \$20 billion for pounds, the U.S. government will need to come up with £10 billion pounds (= the required number of pounds at the $\$2 = \pounds 1$ exchange rate). And if Britons wish to exchange £6 billion for dollars, the U.S. government will have to come up with \$12 billion dollars (= required number of dollars at the $\$2 = \pounds 1$ exchange rate).

Foreign Exchange Market Replaced by Government Peg

As long as the U.S. government is able to come up with the necessary amounts of both dollars (to satisfy exchange requests for pounds) and pounds (to satisfy exchange requests for dollars), the fixed exchange rate will preempt the foreign exchange market. All buying and selling of pounds for dollars or dollars for pounds will take place with the U.S. government. The U.S. government will *become* the dollar-pound foreign exchange market.

There will be no other dollar-pound market because, as long as the U.S. government can maintain the peg, there will be no other exchange rate that buyers and sellers would both simultaneously prefer, and thus no possibility of a given buyer and a given seller ever voluntarily agreeing to exchange dollars for pounds at any other exchange rate. To see why, consider an exchange rate like $\$3 = \pounds 1$. U.K. citizens wishing to convert pounds to dollars would prefer $\$3 = \pounds 1$ to the $\$2 = \pounds 1$ exchange rate being offered by the U.S. government because each of their pounds would convert into \$3 rather than \$2. But would U.K. citizens be able to find anyone willing to take the opposite end of the deal and exchange dollars for pounds at a $\$3 = \pounds 1$ exchange rate? The answer is no because anyone wishing to convert dollars to pounds would be able to go to the U.S. government and exchange money at the rate of $\$2 = \pounds 1$, under which they would only have to give up \$2 (rather than \$3) to buy £1. So while U.K. citizens would prefer any exchange rate that gives them more dollars per pound than the $\$2 = \pounds 1$ rate being offered by the U.S. government, they are not going to find anybody willing to exchange money at those rates. So anybody who wants to exchange pounds for dollars will end up dealing with the U.S. government and exchanging money at the $\$2 = \pounds 1$ fixed rate.

You should take a moment to convince yourself that the reverse is also true: While Americans would prefer an exchange rate that requires them to give up less than \$2 for each £1, no U.K. citizen would willingly accept a rate lower than $\$2 = \pounds 1$ because doing so would mean receiving fewer dollars for their pounds than if they exchanged their pounds at the $\$2 = \pounds 1$ exchange rate being offered by the U.S. government. So everyone wishing to exchange dollars for pounds will also end up dealing with the U.S. government and exchanging money at the $\$2 = \pounds 1$ fixed exchange rate.

Please note, however, that if the U.S. government were ever to stop honoring its pledge to exchange dollars for pounds and pounds for dollars at the $\$2 = \pounds 1$ exchange rate, a private market for foreign exchange would instantly pop back into existence to connect the buyers and sellers of dollars and pounds. Because the exchange rate would be determined by supply and demand, it could end up at an equilibrium value that is substantially different from the value of the fixed exchange rate that was just abandoned.

Official Reserves

A government that opts for a fixed exchange rate typically places its central bank in charge of day-to-day operations. It thus becomes the central bank's task to exchange as much local currency for foreign currency and as much foreign currency for local currency as is necessary each day to maintain the peg.

Satisfying requests to exchange foreign currency for local currency is easy, as the central bank has the legal right to

print up as much local currency as it wants. But to satisfy requests to exchange local currency for foreign currency, the central bank must maintain a stock (inventory) of foreign currency since it can't legally create additional units of any other country's money.

The stock of the particular foreign currency that is used to maintain the fixed exchange rate will be just one component of the **official reserves** that the central bank will maintain for the government. The official reserves will consist not only of stockpiles of various foreign currencies but also stockpiles of bonds issued by foreign governments, gold reserves, and special reserves held at the International Monetary Fund. The stockpiles of foreign currencies are referred to as **foreign-exchange reserves**, or, less formally, FX reserves.

The Sizes of Currency Purchases and Sales

The amount of foreign and local currency that the central bank will have to buy and sell each day will depend on supply and demand. Consider Figure 41.3, in which we assume that the Fed is fixing the dollar-pound exchange rate at $\$2 = \pounds 1$.

Begin by looking at the intersection of demand curve D_1 with supply curve S_1 . If this were a free market, the equilibrium exchange rate (determined by where D_1 intersects S_1) would be equal to $\$2 = \pounds 1$. But because the Fed is preempting the market by guaranteeing to exchange as many pounds for dollars and as many dollars for pounds as anyone might want to exchange at a price of $\$2 = \pounds 1$, there will be no free market for foreign exchange. Instead, the Fed will act as a monopoly currency dealer (middleman) on all currency transactions. It will buy from those who wish to sell and sell to those who wish to buy.

In undertaking those sales, the Fed will find that its reserve of pounds will either remain constant, rise, or fall, depending upon the positions of the demand and supply curves.

FX Reserves Are Constant When Purchases Equal Sales If the demand and supply curves for pounds happen to intersect at the $\$2 = \pounds 1$ value of the fixed exchange rate, the Fed's reserve of pounds will remain unchanged in size. This situation is illustrated in Figure 41.3. Demand curve D_1 happens to intersect supply curve S_1 at the fixed exchange rate of $\$2 = \pounds 1$. That implies that the quantity supplied of pounds and the quantity demanded of pounds will both equal b at the fixed exchange rate of $\$2 = \pounds 1$. So the Fed will be buying and selling an equal number of pounds, which implies that its reserve of pounds will remain constant.

FX Reserves Increase When Sales Exceed Purchases Next, imagine a situation in which the quantity demanded of pounds at the fixed exchange rate exceeds the quantity supplied of pounds at the fixed exchange rate. That happens in Figure 41.3 when the demand curve shifts left to

FIGURE 41.3 Fixed exchange rate with increasing foreign exchange reserves. To maintain a fixed exchange rate of $\$2 = \pounds 1$, the central bank will have to buy whatever amount of pounds sellers supply at that price and sell whatever amount of pounds buyers demand at that price. If the demand curve for pounds shifts left to D_0 , the quantity of pounds that the central bank will have to sell to buyers at the fixed exchange rate will be less than the quantity of pounds b that the central bank will have to buy from sellers at that price. The central bank's reserve of pounds will consequently increase by amount ab . Not shown: As the reserve of pounds increases, so will the domestic money supply of dollars.

D_0 while the supply curve remains at S_1 . In this situation, the Fed will *not* be exchanging equal quantities of pounds for dollars and dollars for pounds. At the fixed $\$2 = \pounds 1$ exchange rate, the quantity demanded of pounds along demand curve D_0 will be a while the quantity supplied of pounds along supply curve S_1 will be b . There will be an excess supply of pounds ab that the Fed will end up owning.

That happens because Fed must satisfy both the buyers' desire to purchase a pounds for dollars and the sellers' desire to sell b pounds for dollars. After satisfying both of those desires, the Fed will find that its reserve of pounds has increased by the amount ab since it will have bought more pounds from suppliers than it sold to demanders. *The general rule is that if the quantity supplied of the foreign currency exceeds the quantity demanded at the fixed exchange rate, the central bank will accumulate foreign currency reserves as it accommodates the excess supply.*

Increasing Reserves = Increasing Domestic Money Supply There is a flip side to accumulating foreign currency reserves: The net amount of local currency will also be increasing. This is because when the Fed buys ab more pounds than it sells, it will have to pay for those extra ab pounds by printing up dollars. Those new dollars initially go into the hands of the people who converted pounds into dollars. But as those people spend the newly created dollars for American goods, services,

and assets, the general level of prices will tend to rise. Other things equal, rising reserves are inflationary.

Locating Increasing Reserves in the Balance of Payments Increases in foreign exchange reserves appear as a negative (–) item in the U.S. balance of payments statement, specifically as U.S. purchases of foreign assets (line 13 of Table 41.1). Increases in FX reserves are a debit because they represent an outflow of dollars.

Please note that in addition to the possibility of obtaining increased FX reserves as part of a fixed exchange rate regime (as in Figure 41.3), central banks and national governments may also increase FX reserves (whether or not they are pegging the exchange rate) by purchasing foreign currency with either domestic tax revenues or by printing up additional domestic currency. Those increases would also go into line 13 as a negative item.

FX Reserves Decrease When Purchases Exceed Sales

Consider Figure 41.4, which reproduces demand curve D_1 and supply curve S_1 from Figure 41.3, but in which we now have a rightward shift of the demand curve from D_1 to D_2 . At the fixed exchange rate of $\$2 = \text{£}1$, there will now be more pounds demanded d than there will be pounds supplied b . As a result of this shortage of pounds, the Fed will find that its reserve of pounds will decrease by bd as it sells

FIGURE 41.4 Fixed exchange rate with decreasing foreign exchange reserves. To maintain a fixed exchange rate of $\$2 = \text{£}1$, the central bank will have to buy whatever amount of pounds sellers supply at that price and sell whatever amount of pounds buyers demand at that price. If the demand curve for pounds shifts right to D_2 , the quantity of pounds d that the central bank will have to sell to buyers at the fixed exchange rate will be less than the quantity of pounds b that the central bank will have to buy from sellers. The central bank's reserve of pounds will consequently decrease by amount bd . Not shown: As the reserve of pounds decreases, so will the domestic money supply of dollars.

more pounds for dollars (point d along demand curve D_2) than it buys pounds for dollars (point b along supply curve S_1). *The general rule is that if the quantity demanded of the foreign currency exceeds the quantity supplied at the fixed exchange rate, the central bank will shed foreign currency reserves as it accommodates the excess demand.*

Decreasing Reserves = Decreasing Domestic Money Supply

The fall in pound reserves will automatically cause a decrease in the supply of dollars in the U.S. economy because as the Fed sells more pounds than it buys, it will receive more dollars in payment for the d pounds that it sells than the number of dollars it has to pay for the b pounds that it buys. Because those extra dollars go into the Fed's vaults, they no longer circulate. So in situations such as the one shown in Figure 41.4, there will be fewer dollars flowing around the U.S. economy and thus a tendency for a lower overall price level. Other things equal, decreasing reserves are deflationary.

Locating Decreasing Reserves in the Balance of Payments

Decreases in foreign exchange reserves appear as a plus (+) item in the U.S. balance of payments statement, specifically as foreign purchases of U.S. assets (line 12 of Table 41.1). The decreases are a credit because they represent an inflow of dollars.

Please note that in addition to FX reserves declining as part of a fixed exchange rate regime (as in Figure 41.4), central banks and national governments may also decrease FX reserves (whether or not they are fixing an exchange rate) by selling them in exchange for the local currency. Any such decreases would also go into line 12 as a positive item.

Small and Alternating Changes in FX Reserves and the Domestic Money Supply

If the periods of time when the Fed is buying more pounds than it sells (such as ab in Figure 41.3) alternate frequently enough with the periods of time when the Fed is selling more pounds than it buys (such as bd in Figure 41.4), then the Fed will not have to worry too much about inflation or deflation because any inflationary pressures caused by buying more pounds than it sells will be offset by deflationary pressures caused by selling more pounds than it buys. If the alternation is often enough and the number of dollars is small enough, then the changes in the domestic money supply caused by changes in FX reserves will have very little effect on the domestic price level.

It is also the case that if the periods of surplus and deficit in pound buying and selling alternate frequently enough or only involve modest quantities, the Fed will not have to worry about there being any long-term trend in the size of its pound reserves. The periods of buying more pounds will offset the periods of selling more pounds and the overall quantity of pound reserves will tend to stay about the same on average as time passes.

As a rule of thumb, the changes in both the domestic money supply and the size of the central bank's FX reserves will tend to be small and offsetting if the fixed exchange rate is close in value to the equilibrium exchange rate that would obtain if a free market determined the exchange rate. When the fixed rate is close to the equilibrium rate, any difference between the number of pounds sold and the number of pounds bought will tend to be small and, consequently, there will be little effect on either the domestic money supply or FX reserves.

Large and Continuous Changes in FX Reserves and the Domestic Money Supply

Major economic difficulties can arise if a nation's fixed exchange rate remains either substantially above or substantially below the equilibrium exchange rate for a long period of time.

Large and Continuous Increases in FX Reserves and the Domestic Money Supply First imagine that the disequilibrium situation depicted in Figure 41.3 continued month after month and perhaps even year after year. With the fixed exchange rate substantially above the equilibrium exchange rate determined by where demand curve D_0 intersects supply curve S_1 , both FX reserves and the local money supply will increase substantially. The continual increase in the local money supply will impel inflation.

If the anticipated increase in inflation is only modest, the central bank may choose to do nothing in response, and just allow the resulting inflation to occur. But if the injections of new dollars are likely to cause too large an increase in inflation, the central bank will have to either:

- Reset the peg lower (at, say, $\$1.9 = \text{£}1$ in Figure 41.3) so that the peg moves closer to the equilibrium exchange rate and thereby reduces the volume of new-dollar creation.
- Abandon the peg altogether so that the equilibrium exchange rate (point c in Figure 41.3) would prevail and new-dollar creation would halt.
- Keep the peg the same, but offset the ab dollars created in Figure 41.3 with other policy interventions that reduce the domestic money supply. These **sterilization** operations can be accomplished by using either open market operations to sell bonds for dollars or by increasing the banking system's reserve requirements so as to limit the creation of checkable-deposit money. The amount of sterilization will depend upon the central bank's preferences. It can range from just a few dollars all the way up to a complete offset of ab . (See the nearby Consider This piece for an example of sterilization in action.)

China's Inflationary Peg

China's economy boomed in the 1990s and 2000s after it abandoned communism for a market-based economy. China also fixed the value of its currency, the yuan, against the dollar and

other foreign currencies to insulate local exporters and investors against exchange rate movements.

The peg that China chose was consistently below the free market equilibrium exchange rate throughout the 2000s so that China's foreign exchange reserves ballooned from just \$165 billion in 2000 to a peak of just over \$4 trillion in 2014.

China did attempt to gradually reset the peg lower, dropping the fixed exchange rate from about 8.3 yuan = \$1 in the early 2000s to about 6.2 yuan = \$1 by 2014. But because the yuan price of a dollar remained higher than equilibrium, China aroused accusations in other countries of unfairly subsidizing its export industries by making the yuan artificially cheap.

China also ensured substantial inflationary pressures at home as the number of yuan soared along with the increasing mountain of FX reserves. Inflation spiked as high as 8 percent despite aggressive sterilization efforts and an increase in the reserve ratio for bank lending from 6 percent to 21.5 percent, which left China with the highest reserve ratio by far of any major economy.

Large and Continuous Decreases in FX Reserves and the Domestic Money Supply

There is an important difference between having large and continuous increases in FX reserves and the domestic money supply on the one hand (Figure 41.3) and having large and continuous decreases in FX reserves and the domestic money supply on the other hand (Figure 41.4). The difference is caused by the fact that a country's central bank can only legally print the domestic currency. It has no right to print any other country's currency. So if its FX reserves are declining, it cannot simply print up more foreign money to make up for an ongoing decline in its FX reserves.

If the central bank finds itself continually in a situation like Figure 41.4, it has to face the reality that its FX reserves might soon be exhausted. If that were to happen, the country would have to abandon its peg and allow the exchange rate to adjust to its free-market equilibrium value. That might not be a catastrophe, but it would mean that the local economy would have to begin dealing with the volatility and risk

associated with a flexible exchange rate. If the central bank wishes to avoid those problems, it will have to figure out a way to either halt, or at least slow, the decline in FX reserves.

One way for the central bank to reduce the rate at which its FX reserves are running out is to reset the peg higher (to, say, $\$2.25 = \pounds 1$ in Figure 41.4). Resetting the peg higher moves the peg closer to the equilibrium exchange rate and thereby reduces the rate at which the central bank's foreign exchange reserves are falling.

Please note, however, that resetting the peg at a higher value will only *slow* the decline in FX reserves if the new value remains below the free-market equilibrium exchange rate. So it is important to consider the policy measures that could be taken to prevent the total exhaustion of the country's FX reserves if the peg cannot be reset all the way up to the free-market equilibrium value.

Trade Policies To maintain a fixed exchange rate, a nation can try to control the flow of trade and finance directly. The United States could try to maintain the $\$2 = \pounds 1$ exchange rate in the face of a shortage of pounds by discouraging imports (thereby reducing the demand for pounds) and encouraging exports (thus increasing the supply of pounds). Imports could be reduced by means of new tariffs or import quotas; special taxes could be levied on the interest and dividends U.S. financial investors receive from foreign investments. Also, the U.S. government could subsidize certain U.S. exports to increase the supply of pounds.

The fundamental problem is that these policies reduce the volume of world trade and change its makeup from what is economically desirable. When nations impose tariffs, quotas, and the like, they lose some of the economic benefits of a free flow of world trade. That loss should not be underestimated: Trade barriers by one nation lead to retaliatory responses from other nations, multiplying the loss.

Exchange Controls and Rationing Another option is to adopt rationing via exchange controls (which are also sometimes referred to as capital controls). Under **exchange controls**, the U.S. government could handle the problem of a pound shortage by requiring that all pounds obtained by U.S. exporters be sold to the federal government. Then the government would allocate or ration this short supply of pounds (represented by xb in Figure 41.4) among various U.S. importers, who demand the quantity xd . This policy would restrict the value of U.S. imports to the amount of foreign exchange earned by U.S. exports. Assuming balance in the capital and financial account, there would then be no balance-of-payments deficit. U.S. demand for British imports with the value bd would simply not be fulfilled.

There are major objections to exchange controls:

- **Distorted trade** Like *trade controls* (tariffs, quotas, and export subsidies), exchange controls would distort the

pattern of international trade away from the pattern suggested by comparative advantage.

- **Favoritism** The process of rationing scarce foreign exchange might lead to government favoritism toward selected importers (big contributors to reelection campaigns, for example).
- **Restricted choice** Controls would limit freedom of consumer choice. The U.S. consumers who prefer Volkswagens might have to buy Chevrolets. The business opportunities for some U.S. importers might be impaired if the government were to limit imports.
- **Black markets** Enforcement problems are likely under exchange controls. U.S. importers might want foreign exchange badly enough to pay more than the $\$2 = \pounds 1$ official rate, setting the stage for black-market dealings between importers and illegal sellers of foreign exchange.

Domestic Macroeconomic Adjustments A final way to maintain a fixed exchange rate would be to use domestic stabilization policies (monetary policy and fiscal policy) to eliminate the shortage of foreign currency. Tax hikes, reductions in government spending, and a high-interest-rate policy would reduce total spending in the U.S. economy and, consequently, domestic income. Because the volume of imports varies directly with domestic income, demand for British goods, and therefore for pounds, would be restrained.

If these “contractionary” policies served to reduce the domestic price level relative to Britain's, U.S. buyers of consumer and capital goods would divert their demands from British goods to U.S. goods, reducing the demand for pounds. Moreover, the high-interest-rate policy would lift U.S. interest rates relative to those in Britain.

Lower prices on U.S. goods and higher U.S. interest rates would increase British imports of U.S. goods and would increase British financial investment in the United States. Both developments would increase the supply of pounds. The combination of a decrease in the demand for and an increase in the supply of pounds would reduce or eliminate the original U.S. balance-of-payments deficit. In Figure 41.4, the new supply and demand curves would intersect at some new equilibrium point on line bd , where the exchange rate remains at $\$2 = \pounds 1$.

Maintaining fixed exchange rates by such means is hardly appealing. The “price” of exchange-rate stability for the United States would be a decline in output, employment, and price levels—in other words, a recession. Eliminating a balance-of-payments deficit and achieving domestic stability are both important national economic goals, but to sacrifice macroeconomic stability simply to defend a currency peg would be to let the tail wag the dog. This chapter's Last Word discusses these concerns in the context of the European monetary

union, which can be thought of as a system of permanently fixed exchange rates.

Confusing Payments Terminology

We know that a nation's balance of payments must always balance. It therefore is understandably confusing when economists or the press occasionally refer to a decrease of FX reserves in a country with a fixed exchange rate as a "balance of payments deficit" or an increase of FX reserves as a "balance of payments surplus." This unfortunate terminology often leads to inaccurate interpretations.

When a central bank fixes the exchange rate, all international payments (for trade, services, assets, remittances, etc.) will go through the central bank. If the quantities of foreign currency demanded and supplied aren't equal, the central bank's FX reserves will necessarily rise or fall, as you know from Figures 41.3 and 41.4.

Where FX reserves are rising, the "balance of payments surplus" terminology leads some people to falsely conclude that the United States is in some way "winning" a battle for international payments. After all, it is achieving a larger pile of wealth in the form of increased FX reserves.

What this mistaken interpretation misses is that the increase in FX reserves was not free. Anything gained by one country in terms of higher FX reserves had to be paid for by giving up assets, goods, or services of *an equal value* to another country. What looks like something achieved—a "balance of payments surplus"—results from a failure to account for the items that had to be given up to obtain the increase in FX reserves. This mistake in interpretation is equivalent to a coin dealer exchanging some rare Roman coins for euros but then only counting the increase in the number of euros in his cash box. That would be foolish because he will be failing to account for the fact that he now has fewer rare Roman coins in his possession. Euros were gained, but Roman coins were lost.

So don't be misled by this confusing terminology if you hear or read it. A **balance of payments deficit** is simply a decrease in FX reserves within the overall balance of payments that takes place when a country on a fixed exchange rate is forced to sell FX reserves in order to maintain its currency peg. A **balance of payments surplus** is simply an increase in FX reserves within the overall balance of payments that takes place when a country on a fixed exchange rate is forced to buy FX reserves in order to maintain its currency peg. The balance of payments will always balance. Any increase or decrease in FX reserves in lines 12 or 13 of the Capital and Financial Account in Table 41.1 will be exactly offset by one or more entries of the same total size, but of the opposite sign in lines 1 through 9 of the Current Account. Flows of goods, services, and transfer payments will perfectly offset any increase or decrease in the stock of FX reserves.

QUICK REVIEW 41.4

- ✓ To circumvent the disadvantages of flexible exchange rates, at times nations have fixed or "pegged" their exchange rates.
- ✓ Under a system of fixed exchange rates, nations set their exchange rates and then maintain them by buying or selling official reserves of currencies, establishing trade barriers, employing exchange controls, or incurring inflation or recession.
- ✓ Under a fixed exchange rate, any increase (decrease) in foreign exchange reserves will automatically generate an accompanying increase (decrease) in the domestic money supply that can cause inflation (deflation) unless it is offset by other policy actions, such as sterilization.

The Current Exchange Rate System: The Managed Float

L041.5 Explain the current system of managed floating exchange rates.

Over the past 130 years, the world's nations have used three different exchange-rate systems. From 1879 to 1934, most nations used a gold standard, which implicitly created fixed exchange rates. From 1944 to 1971, most countries participated in the Bretton Woods system, which was a fixed-exchange-rate system indirectly tied to gold. And since 1971, most have used managed floating exchange rates, which mix mostly flexible exchange rates with occasional **currency interventions** during which a government buys or sells foreign exchange in the foreign exchange market in order to alter either supply or demand in a way that will push the exchange rate in the direction the government wants. Naturally, our focus here is on the current exchange-rate system. However, the history of the previous systems and why they broke down is highly fascinating.

The current international exchange-rate system (1971–present) is an "almost" flexible system called **managed floating exchange rates**. Exchange rates among major currencies are free to float to their equilibrium market levels, but nations occasionally use currency interventions in the foreign exchange market to stabilize or alter market exchange rates.

Normally, the major trading nations allow their exchange rates to float up or down to equilibrium levels based on supply and demand in the foreign exchange market. They recognize that changing economic conditions among nations require continuing changes in equilibrium exchange rates. They rely on freely operating foreign exchange markets to accomplish the necessary adjustments. The result has been considerably more volatile exchange rates than those during the Bretton Woods era.

But nations also recognize that certain trends in the movement of equilibrium exchange rates may be at odds with national or international objectives. On occasion, nations therefore intervene in the foreign exchange market by buying or selling large amounts of specific currencies. This way, they can “manage” or stabilize exchange rates by influencing currency demand and supply. In some cases, the interventions are sterilized via open market operations to prevent any change in the domestic money supply.

The current exchange-rate system is thus an “almost” flexible exchange-rate system. The “almost” refers mainly to the occasional currency interventions by governments; it also refers to the fact that the actual system is more complicated than described. While the major currencies such as dollars, euros, pounds, and yen fluctuate in response to changing supply and demand, some developing nations peg their currencies to the dollar and allow their currencies to fluctuate with it against other currencies. Also, some nations peg the value of their currencies to a “basket” or group of other currencies.

How well has the managed float worked? It has both proponents and critics.

In Support of the Managed Float Proponents of the managed-float system argue that it has functioned far better than many experts anticipated. Skeptics had predicted that fluctuating exchange rates would reduce world trade and finance. But in real terms, world trade under the managed float has grown tremendously over the past several decades. Moreover, as supporters are quick to point out, currency crises such as those in Mexico and southeast Asia in the last half of the 1990s were not the result of the floating-exchange-rate system itself. Rather, the abrupt currency devaluations and depreciations resulted from internal problems in those nations, in conjunction with the nations’ tendency to peg their currencies to the dollar or to a basket of currencies. In some cases, flexible exchange rates would have made these adjustments far more gradual.

Proponents also point out that the managed float has weathered severe economic turbulence that might have caused a fixed-rate system to break down. Such events as extraordinary oil price increases in 1973–1974 and again in 1981–1983, inflationary recessions in several nations in the mid-1970s, major national recessions in the early 1980s, and large U.S. budget deficits in the 1980s and the first half of the 1990s all caused substantial imbalances in international trade and finance, as did the large U.S. budget deficits and soaring world oil prices that occurred in the middle of the first decade of the 2000s. The U.S. financial crisis and the severe recession of 2007–2009 greatly disrupted world trade. Flexible rates enabled the system to adjust to all these events, whereas the same events would have put unbearable pressures on a fixed-rate system.

Concerns with the Managed Float There is still much sentiment in favor of greater exchange-rate stability. Those favoring more stable exchange rates see problems with the current system. They argue that the excessive volatility of exchange rates under the managed float threatens the prosperity of economies that rely heavily on exports. Several financial crises in individual nations (for example, Mexico, South Korea, Indonesia, Thailand, Russia, and Brazil) were exacerbated by abrupt changes in exchange rates. These crises have led to massive “bailouts” of those economies via loans from the International Monetary Fund (IMF). But the availability of IMF bailouts may spur moral hazard. Nations may undertake risky and inappropriate economic policies because they expect the IMF to bail them out if problems arise. Moreover, some exchange-rate volatility has occurred even when underlying economic and financial conditions were relatively stable, suggesting that speculation plays too large a role in determining exchange rates.

Skeptics say the managed float is basically a “nonsystem” because the guidelines as to what each nation may or may not do with its exchange rates are not specific enough to keep the system working in the long run. Nations inevitably will be tempted to intervene in the foreign exchange market, not merely to smooth out short-term fluctuations in exchange rates but to prop up their currency if it is chronically weak or to manipulate the exchange rate to achieve domestic stabilization goals.

So what are we to conclude? Flexible exchange rates have not worked perfectly, but they have not failed miserably. Thus far they have survived, and no doubt have eased, several major shocks to the international trading system. Meanwhile, the “managed” part of the float has given nations some sense of control over their collective economic destinies. On balance, most economists favor continuation of the present system of “almost” flexible exchange rates.

QUICK REVIEW 41.5

- ✓ The managed floating system of exchange rates (1971–present) relies on foreign exchange markets to establish equilibrium exchange rates.
- ✓ Under the system, nations can buy and sell official reserves of foreign currency to stabilize short-term changes in exchange rates or to correct exchange-rate imbalances that are negatively affecting the world economy.
- ✓ Proponents point out that international trade and investment have grown tremendously under the system. Critics say that it is a “nonsystem” and argue that the exchange rate volatility allowed under the managed float discourages international trade and investment. That is, trade and investment would be even larger if exchange rates were more stable.

Recent U.S. Trade Deficits

LO41.6 Identify the causes and consequences of recent U.S. trade deficits.

As shown in Figure 41.5a, the United States has experienced large and persistent trade deficits in recent years. These deficits rose rapidly between 2002 and 2006, with the trade deficit on goods and services peaking at \$761 billion in 2006.

FIGURE 41.5 U.S. trade deficits, 2002–2015. (a) The United States experienced large deficits in *goods* and in *goods and services* between 2002 and 2012. (b) The U.S. current account, generally reflecting the goods and services deficit, was also in substantial deficit. Although reduced significantly by the recession of 2007–2009, large current account deficits are expected to continue for many years to come.

Source: Bureau of Economic Analysis, www.bea.gov.

The trade deficit on goods and services then declined precipitously to just \$383 billion in 2009 as consumers and businesses greatly curtailed their purchases of imports during the recession of 2007–2009. As the economy recovered from the recession, the trade deficit on goods and services began rising again and reached \$500 billion in 2015. The current account deficit (Figure 41.5b) reached a record high of \$800 billion in 2006, and that amount was 6.0 percent of GDP. The current account deficit declined to \$382 billion—2.6 percent of GDP—in the recession year 2009. After the recession, the current account deficit expanded slowly, to \$486 billion in 2015. But because GDP had also been growing, the 2015 current account deficit amounted to 2.7 percent of GDP, or about the same percentage as in 2009.

Causes of the Trade Deficits

The large U.S. trade deficits have several causes. First, the U.S. economy expanded more rapidly between 2002 and 2007 than the economies of several U.S. trading partners. The strong U.S. income growth that accompanied that economic growth enabled Americans to greatly increase their purchases of imported products. In contrast, Japan and some European nations suffered recession or experienced relatively slow income growth over that same period. So consumers in those countries increased their purchases of U.S. exports much less rapidly than Americans increased their purchases of foreign imports.

Another factor explaining the large trade deficits is the enormous U.S. trade imbalance with China. In 2015 the United States imported \$366 billion more of goods and services from China than it exported to China. Even in the recession year 2009, the trade deficit with China was \$220 billion. The 2015 deficit with China was 82 percent larger than the combined deficits with Mexico (\$58 billion), Germany (\$74 billion), and Japan (\$69 billion). The United States is China's largest export market, and although China has greatly increased its imports from the United States, its standard of living has not yet risen sufficiently for its households to afford large quantities of U.S. products. Adding to the problem, China's government has fixed the exchange rate of its currency, the yuan, to a basket of currencies that includes the U.S. dollar. Therefore, China's large trade surpluses with the United States have not caused the yuan to appreciate much against the U.S. dollar. Greater appreciation of the yuan would have made Chinese goods more expensive in the United States and reduced U.S. imports from China. In China a stronger yuan would have reduced the dollar price of U.S. goods and increased Chinese purchases of U.S. exports. That combination—reduced U.S. imports from China and increased U.S. exports to China—would have reduced the large U.S. trade imbalance.

A declining U.S. saving rate (= saving/total income) also contributed to the large U.S. trade deficits. Up until the recession of 2007–2009, the U.S. saving rate declined substantially,

while its investment rate ($=$ investment/total income) increased. The gap between U.S. investment and U.S. saving was filled by foreign purchases of U.S. real and financial assets, which created a large surplus on the U.S. capital and financial account. Because foreign savers were willing to finance a large part of U.S. investment, Americans were able to save less and consume more. Part of that added consumption spending was on imported goods.

Finally, many foreigners simply view U.S. assets favorably because of the relatively high risk-adjusted rates of return they provide. The purchase of those assets provides foreign currency to Americans that enables them to finance their strong appetite for imported goods. The capital account surpluses, therefore, may partially cause the high U.S. trade deficits, not just result from those high deficits. The point is that the causes of the high U.S. trade deficits are numerous and not so easy to disentangle.

Implications of U.S. Trade Deficits

The prerecession U.S. trade deficits were the largest ever run by a major industrial nation. Whether the large trade deficits should be of significant concern to the United States and the rest of the world is debatable. Most economists see both benefits and costs to trade deficits.

Increased Current Consumption At the time a trade deficit or a current account deficit is occurring, American consumers benefit. A trade deficit means that the United States is receiving more goods and services as imports from abroad than it is sending out as exports. Taken alone, a trade deficit allows the United States to consume outside its production possibilities curve. It augments the domestic standard of living. But here is a catch: The gain in present consumption may come at the expense of reduced future consumption. When and if the current account deficit declines, Americans may have to consume less than before and perhaps even less than they produce.

Increased U.S. Indebtedness A trade deficit is considered unfavorable because it must be financed by borrowing from the rest of the world, selling off assets, or dipping into official reserves. Recall that current account deficits are financed by surpluses in the capital and financial accounts. Such surpluses require net inpayments of dollars to buy U.S. assets, including debt issued by Americans. Therefore, when U.S. exports are insufficient to finance U.S. imports, the United States increases both its debt to people abroad and the value of foreign claims against assets in the United States. Financing of the U.S. trade deficit has resulted in a larger foreign accumulation of claims against U.S. financial and real assets than the U.S. claim against foreign assets. In 2015, foreigners owned about \$7.4 trillion more of U.S. assets (corporations, land, stocks, bonds, loan notes) than U.S. citizens and institutions owned of foreign assets.

If the United States wants to regain ownership of these domestic assets, at some future time it will have to export more than it imports. At that time, domestic consumption will be lower because the United States will need to send more of its output abroad than it receives as imports. Therefore, the current consumption gains delivered by U.S. current account deficits may mean permanent debt, permanent foreign ownership, or large sacrifices of future consumption.

We say “may mean” above because the foreign lending to U.S. firms and foreign investment in the United States increases the U.S. capital stock. U.S. production capacity therefore might increase more rapidly than otherwise because of a large surplus on the capital and financial account. Faster increases in production capacity and real GDP enhance the economy’s ability to service foreign debt and buy back real capital, if that is desired.

Trade deficits therefore are a mixed blessing. The long-term impacts of the record-high U.S. trade deficits are largely unknown. That “unknown” worries some economists, who are concerned that foreigners will lose financial confidence in the United States. If that happens, they would restrict their lending to American households and businesses and also reduce their purchases of U.S. assets. Both actions would decrease the demand for U.S. dollars in the foreign exchange market and cause the U.S. dollar to depreciate. A sudden, large depreciation of the U.S. dollar might disrupt world trade and negatively affect economic growth worldwide. Other economists, however, downplay this scenario. Because any decline in the U.S. capital and financial account surplus is automatically met with a decline in the current account deficit, U.S. net exports would rise and the overall impact on the American economy would be slight.

QUICK REVIEW 41.6

- ✓ The United States has had large trade deficits in recent decades.
- ✓ Causes include (a) more rapid income growth in the United States than in Japan and some European nations, resulting in expanding U.S. imports relative to exports; (b) the emergence of a large trade deficit with China; (c) continuing large trade deficits with oil-exporting nations; and (d) a large surplus in the capital and financial account, which enabled Americans to reduce their saving and buy more imports.
- ✓ The severe recession of 2007–2009 in the United States substantially lowered the U.S. trade deficit by reducing American spending on imports.
- ✓ U.S. trade deficits have produced current increases in the living standards of U.S. consumers but the accompanying surpluses on the capital and financial account have increased U.S. debt to the rest of the world and increased foreign ownership of assets in the United States.

Are Common Currencies Common Sense?

A Shared Currency Precludes Independent Monetary Policies and External Adjustments

When countries use different currencies, international trade is hampered by the deadweight cost of currency-conversion fees, difficulties comparing costs when prices are given in multiple currencies, and exchange-rate risk.

Taken together, these problems suggest a simple solution: Why not use the same currency?

The 19 nations that are members of the eurozone did just that, eliminating their respective local currencies in favor of the euro. When they did, cross-border trade and investment surged, improving the economic prospects of all member nations. Unfortunately, life is full of costs as well as benefits. So while the eurozone countries did dramatically improve international trade and investment among their members, they incurred two major costs.

The Loss of Independent Monetary Policy When a country joins the European Monetary Union, it retains its own central bank, but cedes control over monetary policy to the central authority of the European Central Bank (ECB). To see why this can be problematic, consider a situation in which eurozone member Slovakia is in a recession while the rest of Europe is booming. The ECB has to set a single policy for all members. Because the large majority have booming economies, the ECB will choose to either keep interest rates constant or even raise them—just the opposite of what recessionary Slovakia needs.

The same problem confronts countries such as Zimbabwe, Panama, and El Salvador that have opted to use the U.S. dollar. By switching to U.S. dollars, they have ceded control over monetary policy to the Fed—which will put zero weight on their various local business cycles when setting monetary policy and interest rates for the United States.

The Loss of External Adjustments A country that joins a currency union also loses the ability to maintain competitiveness in international trade by making “external adjustments” to its current account balance. As an example, suppose that Greek goods and services are expensive relative to those produced by other eurozone countries because Greece has restrictive labor laws, low industrial productivity, unnecessarily high tax rates, and a bloated and corrupt public sector. These high costs will tend to cause both a trade deficit and a current account deficit in Greece because Greek consumers will favor less expensive foreign imports while at the same time Greek exporters will be hampered by high production costs.

This situation is not overly problematic if the Greek economy is growing. But if a recession starts, it would be helpful for Greece to figure out a way to boost its competitiveness in international trade and thereby increase the aggregate demand for its goods and services.

Source: © Maryna Pleshkun/Shutterstock.com

If Greece had retained its own currency, the Greek government could simply intervene in the foreign exchange market and devalue the Greek currency. The devaluation would be equivalent to putting all Greek goods and services on sale simultaneously, thereby making them more attractive to foreign consumers. At the same time, the price of foreign goods in Greece would rise, thereby causing local consumers to substitute domestic goods and services for imports. Aggregate demand within Greece would increase. The current account would move toward surplus. The “external adjustment” of devaluation would help Greece with its recession.

But Greece can’t devalue; it no longer has its own currency. It can’t use the external adjustment of devaluation to help resolve its high costs and lack of competitiveness. Its only way forward will be “internal adjustments” in which changes in the domestic economy lower the Greek cost structure so as to make its products internationally competitive again.

The Greek government could attempt to lower taxes, liberalize labor laws, and reform the bloated and corrupt public sector. But in most countries, those sorts of “structural changes” will be difficult to implement because of strong resistance by special interests or because of prior spending commitments. If they cannot be implemented, a country like Greece will be left with only the most painful type of internal adjustment: a recession-induced deflation in which falling aggregate demand slowly leads to a lower domestic price level. The recession will end, but only after downward price stickiness is overcome and the price level falls by enough to induce consumers both at home and abroad to buy more Greek products.

SUMMARY

LO41.1 Explain how currencies of different nations are exchanged when international transactions take place.

International financial transactions involve trade either in currently produced goods and services or in preexisting assets. Exports of goods, services, and assets create inflows of money, while imports cause outflows of money. If buyers and sellers use different currencies, then foreign exchange transactions take place so that the exporter can be paid in his or her own currency.

LO41.2 Analyze the balance sheet the United States uses to account for the international payments it makes and receives.

The balance of payments records all international trade and financial transactions taking place between a given nation and the rest of the world. The balance on goods and services (the trade balance) compares exports and imports of both goods and services. The current account balance includes not only goods and services transactions but also net investment income and net transfers.

The capital and financial account includes (a) the net amount of the nation's debt forgiveness and (b) the nation's sale of real and financial assets to people living abroad less its purchases of real and financial assets from foreigners.

The current account and the capital and financial account always sum to zero. A deficit in the current account is always offset by a surplus in the capital and financial account. Conversely, a surplus in the current account is always offset by a deficit in the capital and financial account.

LO41.3 Discuss how exchange rates are determined in currency markets that have flexible exchange rates.

Flexible or floating exchange rates between international currencies are determined by the demand for and supply of those currencies. Under flexible rates, a currency will depreciate or appreciate as a result of changes in tastes, relative income changes, relative changes in inflation rates, relative changes in real interest rates, and speculation. But the fluctuations in the exchange rate that occur under a flexible exchange rate system introduce uncertainty that can reduce the volume of international trade and destabilize the local economy.

LO41.4 Describe the differences between flexible and fixed exchange rates, including how changes in foreign exchange reserves bring about automatic changes in the domestic money supply under a fixed exchange rate.

Some countries have their central banks fix, or peg, their exchange rates to a particular value in order to eliminate the uncertainty about future exchange rates that arises under a floating exchange rate system. Because fixing requires buying and selling foreign currencies, the central bank will maintain reserves (stockpiles) of various foreign currencies. Those foreign exchange (FX) reserves

are a subset of a nation's overall collection of official reserves, which can include gold, foreign bonds, and special reserves held with the International Monetary Fund in addition to its holdings of FX reserves.

To maintain a fixed exchange rate, a central bank will simultaneously stand ready to sell as much foreign currency as buyers demand at the fixed exchange rate and buy as much foreign currency as sellers wish to supply at the fixed exchange rate. Those amounts will only be equal if the fixed exchange rate happens to equal the free-market exchange rate that would prevail if the country let the currency float. In other cases, the central bank's stockpile of foreign currency will either be rising or falling.

If FX reserves fall continuously, they may become exhausted. In such situations, the country will have to either abandon the peg, alter the peg, invoke protectionist trade policies, engage in exchange controls, or endure undesirable domestic macroeconomic adjustments.

Countries operating fixed exchange rates must also grapple with the fact that whenever the fixed exchange rate differs from the free-market exchange rate, the domestic money supply will be either rising or falling in tandem with its foreign currency (FX) reserves. That rise or fall in the domestic money supply will cause inflationary or deflationary pressures that policymakers will have to either accept or offset via open-market sterilization operations (bond purchases or sales) or changes in bank reserve ratios.

LO41.5 Explain the current system of managed floating exchange rates.

Since 1971 the world's major nations have used a system of managed floating exchange rates. Market forces generally set rates, although governments intervene with varying frequency to alter their exchange rates.

LO41.6 Identify the causes and consequences of recent U.S. trade deficits.

Between 1997 and 2007, the United States had large and rising trade deficits, which are projected to last well into the future. Causes of the trade deficits include (a) more rapid income growth in the United States than in Japan and some European nations, resulting in expanding U.S. imports relative to exports; (b) the emergence of a large trade deficit with China; (c) continuing large trade deficits with oil-exporting nations; and (d) a large surplus in the capital and financial account, which enabled Americans to reduce their saving and buy more imports. The severe recession of 2007–2009 in the United States substantially lowered the U.S. trade deficit by reducing American spending on imports.

U.S. trade deficits have produced current increases in the living standards of U.S. consumers. The accompanying surpluses on the capital and financial account have increased U.S. debt to the rest of the world and increased foreign ownership of assets in the United States. This greater foreign investment in the United States, however, has undoubtedly increased U.S. production possibilities.

REVIEW QUESTIONS

1. An American company wants to buy a television from a Chinese company. The Chinese company sells its TVs for 1,200 yuan each. The current exchange rate between the U.S. dollar and the Chinese yuan is $\$1 = 6$ yuan. How many dollars will the American company have to convert into yuan to pay for the television? **LO41.1**
 - a. \$7,200.
 - b. \$1,200.
 - c. \$200.
 - d. \$100.
2. Suppose that a country has a trade surplus of \$50 billion, a balance on the capital account of \$10 billion, and a balance on the current account of $-\$200$ billion. The balance on the capital and financial account will be: **LO41.2**
 - a. \$10 billion.
 - b. \$50 billion.
 - c. \$200 billion.
 - d. $-\$200$ billion.
3. The exchange rate between the U.S. dollar and the British pound starts at $\$1 = \pounds 0.5$. It then changes to $\$1 = \pounds 0.75$. Given this change, we would say that the U.S. dollar has _____ while the British pound has _____. **LO41.3**
 - a. Depreciated; appreciated.
 - b. Depreciated; depreciated.
 - c. Appreciated; depreciated.
 - d. Appreciated; appreciated.
4. A meal at a McDonald's restaurant in New York costs \$8. The identical meal at a McDonald's restaurant in London costs £4. According to the purchasing-power-parity theory of exchange rates, the exchange rate between U.S. dollars and British pounds should tend to move toward: **LO41.3**
 - a. $\$2 = \pounds 1$.
 - b. $\$1 = \pounds 2$.
 - c. $\$4 = \pounds 1$.
 - d. $\$1 = \pounds 4$.
5. Suppose that the Fed is fixing the dollar-pound exchange rate at $\$2.50 = \pounds 1$. If the Fed's reserve of pounds falls by £500 million, by how much would the supply of dollars increase, all other things equal? **LO41.3**
6. Diagram a market in which the equilibrium dollar price of 1 unit of fictitious currency zee (Z) is \$5 (the exchange rate is $\$5 = Z1$). Then show on your diagram a decline in the demand for zee. **LO41.4**
 - a. Referring to your diagram, discuss the adjustment options the United States would have in maintaining the exchange rate at $\$5 = Z1$ under a fixed-exchange-rate system.
 - b. Suppose that the Fed's FX reserves increase by 40 million zeas as a result of the decline in demand. How many millions of dollars worth of bonds will the Fed have to sell in order to sterilize the accompanying increase in the domestic money supply?
7. Suppose that the government of China is currently fixing the exchange rate between the U.S. dollar and the Chinese yuan at a rate of $\$1 = 6$ yuan. Also suppose that at this exchange rate, the people who want to convert dollars to yuan are asking to convert \$10 billion per day of dollars into yuan, while the people who are wanting to convert yuan into dollars are asking to convert 36 billion yuan into dollars. What will happen to the size of China's official reserves of dollars? **LO41.4**
 - a. Increase.
 - b. Decrease.
 - c. Stay the same.
8. Suppose that a country follows a managed-float policy but that its exchange rate is currently floating freely. In addition, suppose that it has a massive current account deficit. Other things equal, are its official reserves increasing, decreasing, or staying the same? If it decides to engage in a currency intervention to reduce the size of its current account deficit, will it buy or sell its own currency? As it does so, will its official reserves of foreign currencies get larger or smaller? **LO41.5**
9. If the economy booms in the United States while going into recession in other countries, the U.S. trade deficit will tend to _____. **LO41.6**
 - a. Increase.
 - b. Decrease.
 - c. Remain the same.
10. Other things equal, if the United States continually runs trade deficits, foreigners will own _____ U.S. assets. **LO41.6**
 - a. More and more.
 - b. Less and less.

- d. Did the dollar appreciate or did it depreciate relative to the loonie between years 1 and 2?
- e. Which one of the following could have caused the change in relative values of the dollar (used in the United States) and the loonie (used in Canada) between years 1 and 2: (1) More rapid inflation in the United States than in Canada, (2) an increase in the real interest rate in the United States but not in Canada, or (3) faster income growth in the United States than in Canada?
4. Suppose that the current Canadian dollar (CAD) to U.S. dollar exchange rate is $\$0.85 \text{ CAD} = \1 US and that the U.S. dollar price of an Apple iPhone is \$300. What is the Canadian dollar price of an iPhone? Next, suppose that the CAD to U.S. dollar exchange rate moves to $\$0.96 \text{ CAD} = \1 US . What is the new Canadian dollar price of an iPhone? Other things equal, would you expect Canada to import more or fewer iPhones at the new exchange rate? **LO41.3**
5. Return to problem 3 and assume that the exchange rate is fixed at 110. In year 1, what would be the minimum initial size of the U.S. reserve of loonies such that the United States could maintain the peg throughout the year? What about the minimum initial size that would be necessary at the start of year 2? Next, consider only the data for year 1. What peg should the U.S. set if it wants the fixed exchange rate to increase the domestic money supply by \$1.2 trillion? **LO41.6**

Previous International Exchange-Rate Systems

LO41.7 Explain how exchange rates worked under the gold standard and Bretton Woods.

This chapter discussed the current system of managed floating exchange rates in some detail. But before this system began in 1971, the world had previously used two other exchange rate systems: the gold standard, which implicitly created fixed exchange rates, and the Bretton Woods system, which was an explicit fixed-rate system indirectly tied to gold. Because the features and problems of these two systems help explain why we have the current system, they are well worth knowing more about.

The Gold Standard: Fixed Exchange Rates

Between 1879 and 1934 the major nations of the world adhered to a fixed-rate system called the **gold standard**. Under this system, each nation must:

- Define its currency in terms of a quantity of gold.
- Maintain a fixed relationship between its stock of gold and its money supply.
- Allow gold to be freely exported and imported.

If each nation defines its currency in terms of gold, the various national currencies will have fixed relationships to one another. For example, if the United States defines \$1 as worth 25 grains of gold, and Britain defines £1 as worth 50 grains of gold, then a British pound is worth 2×25 grains, or \$2. This exchange rate was fixed under the gold standard. The exchange rate did not change in response to changes in currency demand and supply.

Gold Flows If we ignore the costs of packing, insuring, and shipping gold between countries, under the gold standard the rate of exchange would not vary from this $\$2 = \text{£}1$ rate. No one in the United States would pay more than $\$2 = \text{£}1$ because 50 grains of gold could always be bought for \$2 in the United States and sold for £1 in Britain. Nor would the British pay more than £1 for \$2. Why should they when they could buy 50 grains of gold in Britain for £1 and sell it in the United States for \$2?

Under the gold standard, the potential free flow of gold between nations resulted in fixed exchange rates.

Domestic Macroeconomic Adjustments When currency demand or supply changes, the gold standard requires

domestic macroeconomic adjustments to maintain the fixed exchange rate. To see why, suppose that U.S. tastes change such that U.S. consumers want to buy more British goods. The resulting increase in the demand for pounds creates a shortage of pounds in the United States (recall Figure 41.4), implying a U.S. balance-of-payments deficit.

What will happen? Remember that the rules of the gold standard prohibit the exchange rate from moving from the fixed $\$2 = \text{£}1$ rate. The rate cannot move to, say, a new equilibrium at $\$3 = \text{£}1$ to correct the imbalance. Instead, gold will flow from the United States to Britain to correct the payments imbalance.

But recall that the gold standard requires that participants maintain a fixed relationship between their domestic money supplies and their quantities of gold. The flow of gold from the United States to Britain will require a reduction of the money supply in the United States. Other things equal, that will reduce total spending in the United States and lower U.S. real domestic output, employment, income, and, perhaps, prices. Also, the decline in the money supply will boost U.S. interest rates.

The opposite will occur in Britain. The inflow of gold will increase the money supply, and this will increase total spending in Britain. Domestic output, employment, income, and, perhaps, prices will rise. The British interest rate will fall.

Declining U.S. incomes and prices will reduce the U.S. demand for British goods and therefore reduce the U.S. demand for pounds. Lower interest rates in Britain will make it less attractive for U.S. investors to make financial investments there, also lessening the demand for pounds. For all these reasons, the demand for pounds in the United States will decline. In Britain, higher incomes, prices, and interest rates will make U.S. imports and U.S. financial investments more attractive. In buying these imports and making these financial investments, British citizens will supply more pounds in the exchange market.

In short, domestic macroeconomic adjustments in the United States and Britain, triggered by the international flow of gold, will produce new demand and supply conditions for pounds such that the $\$2 = \text{£}1$ exchange rate is maintained. After all the adjustments are made, the United States will not have a payments deficit and Britain will not have a payments surplus.

So the gold standard has the advantage of maintaining stable exchange rates and correcting balance-of-payments

deficits and surpluses automatically. However, its critical drawback is that nations must accept domestic adjustments in such distasteful forms as unemployment and falling incomes, on the one hand, or inflation, on the other hand. Under the gold standard, a nation's money supply is altered by changes in supply and demand in currency markets, and nations cannot establish their own monetary policy in their own national interest. If the United States, for example, were to experience declining output and income, the loss of gold under the gold standard would reduce the U.S. money supply. That would increase interest rates, retard borrowing and spending, and produce further declines in output and income.

Collapse of the Gold Standard The gold standard collapsed under the weight of the worldwide Depression of the 1930s. As domestic output and employment fell worldwide, the restoration of prosperity became the primary goal of afflicted nations. They responded by enacting protectionist measures to reduce imports. The idea was to get their economies moving again by promoting consumption of domestically produced goods. To make their exports less expensive abroad, many nations redefined their currencies at lower levels in terms of gold. For example, a country that had previously defined the value of its currency at 1 unit = 25 grains of gold might redefine it as 1 unit = 10 grains of gold. Such redefining is an example of **devaluation**—a deliberate action by government to reduce the international value of its currency. A series of such devaluations in the 1930s meant that exchange rates were no longer fixed. That violated a major tenet of the gold standard, and the system broke down.

The Bretton Woods System

The Great Depression and the Second World War left world trade and the world monetary system in shambles. To lay the groundwork for a new international monetary system, in 1944, major nations held an international conference at Bretton Woods, New Hampshire. The conference produced a commitment to a modified fixed-exchange-rate system called an *adjustable-peg system*, or, simply, the **Bretton Woods system**. The new system sought to capture the advantages of the old gold standard (fixed exchange rate) while avoiding its disadvantages (painful domestic macroeconomic adjustments).

Furthermore, the conference created the **International Monetary Fund (IMF)** to make the new exchange-rate system feasible and workable. The new international monetary system managed through the IMF prevailed with modifications until 1971. (The IMF still plays a basic role in international finance; in recent years it has performed a

major role in providing loans to developing countries, nations experiencing financial crises, and nations making the transition from communism to capitalism.)

IMF and Pegged Exchange Rates How did the adjustable-peg system of exchange rates work? First, as with the gold standard, each IMF member had to define its currency in terms of gold (or dollars), thus establishing rates of exchange between its currency and the currencies of all other members. In addition, each nation was obligated to keep its exchange rate stable with respect to every other currency. To do so, nations would have to use their official currency reserves to intervene in foreign exchange markets.

Assume again that the U.S. dollar and the British pound were “pegged” to each other at $\$2 = \pounds 1$. And suppose again that the demand for pounds temporarily increases so that a shortage of pounds occurs in the United States (the United States has a balance-of-payments deficit). How can the United States keep its pledge to maintain a $\$2 = \pounds 1$ exchange rate when the new equilibrium rate is, say, $\$3 = \pounds 1$? As we noted previously, the United States can supply additional pounds to the exchange market, increasing the supply of pounds such that the equilibrium exchange rate falls back to $\$2 = \pounds 1$.

Under the Bretton Woods system, there were three main sources of the needed pounds:

- **Official reserves** The United States might currently possess pounds in its official reserves as the result of past actions against a payments surplus.
- **Gold sales** The U.S. government might sell some of its gold to Britain for pounds. The proceeds would then be offered in the exchange market to augment the supply of pounds.
- **IMF borrowing** The needed pounds might be borrowed from the IMF. Nations participating in the Bretton Woods system were required to make contributions to the IMF based on the size of their national income, population, and volume of trade. If necessary, the United States could borrow pounds on a short-term basis from the IMF by supplying its own currency as collateral.

Fundamental Imbalances: Adjusting the Peg The Bretton Woods system recognized that from time to time a nation may be confronted with persistent and sizable balance-of-payments problems that cannot be corrected through the means listed above. In such cases, the nation would eventually run out of official reserves and be unable to maintain its current fixed exchange rate. The Bretton Woods remedy was correction by devaluation, that is, by an “orderly” reduction of the nation's pegged exchange rate. Also, the IMF allowed

each member nation to alter the value of its currency by 10 percent, on its own, to correct a so-called fundamental (persistent and continuing) balance-of-payments deficit. Larger exchange-rate changes required the permission of the Fund's board of directors.

By requiring approval of significant rate changes, the Fund guarded against arbitrary and competitive currency devaluations by nations seeking only to boost output in their own countries at the expense of other countries. In our example, devaluation of the dollar would increase U.S. exports and lower U.S. imports, helping to correct the United States' persistent payments deficit.

Demise of the Bretton Woods System Under this adjustable-peg system, nations came to accept gold and the dollar as international reserves. The acceptability of gold as an international medium of exchange derived from its earlier use under the gold standard. Other nations accepted the dollar as international money because the United States had accumulated large quantities of gold, and between 1934 and 1971 it maintained a policy of buying gold from, and selling gold to, foreign governments at a fixed price of \$35 per ounce. The dollar was convertible into gold on demand, so the dollar came to be regarded as a substitute for gold, or “as good as gold.” The discovery of new gold was limited, but a growing volume of dollars helped facilitate the expanding volume of world trade during this period.

But a major problem arose. The United States had persistent payments deficits throughout the 1950s and 1960s. Those deficits were financed in part by U.S. gold reserves but mostly by payment of U.S. dollars. As the amount of dollars held by foreigners soared and the U.S. gold reserves dwindled, other nations began to question whether the dollar was really “as good as gold.” The ability of the United States to continue to convert dollars into gold at \$35 per ounce became increasingly doubtful, as did the role of dollars as international monetary reserves. Thus the dilemma was: To maintain the dollar as a reserve medium, the U.S. payments deficit had to be eliminated. But elimination of the payments deficit would remove the source of additional dollar reserves and thus limit the growth of international trade and finance.

The problem culminated in 1971 when the United States ended its 37-year-old policy of exchanging gold for dollars at \$35 per ounce. It severed the link between gold and the international value of the dollar, thereby “floating” the dollar and letting market forces determine its value. The floating of the dollar withdrew U.S. support from the Bretton Woods system of fixed exchange rates and effectively ended the system. Nearly all major currencies began to float. This led to the current regime of “managed floating exchange rates” that is described at length in this chapter.

APPENDIX SUMMARY

LO41.7 Explain how exchange rates worked under the gold standard and Bretton Woods.

Before the current system of managed floating exchange rates started in 1971, several different international monetary systems were used.

Between 1879 and 1934, most major trading nations were on the gold standard, in which each nation fixed an exchange rate between its currency and gold. With each nation's currency fixed to gold, the system also implicitly set fixed exchange rates between different national currencies.

Any balance-of-payments imbalance would automatically lead to offsetting international flows of gold. This, in turn, led to automatically occurring domestic macroeconomic adjustments as the country exporting gold automatically encountered a decrease in its money supply while the country importing gold automatically felt an increase in its money supply. When the Great Depression hit, many countries found these automatic adjustments too hard to bear and they abandoned the gold standard.

The Bretton Woods system was implemented after the end of the Second World War and lasted until 1971. Under this system, the United States fixed the value of the U.S. dollar to gold at a rate of \$35 per ounce. Other countries then set fixed exchange rates with the dollar so that their currencies were indirectly fixed to gold through the dollar.

The International Monetary Fund was created to administer the Bretton Woods system, which had some flexibility because exchange rates between countries could be adjusted to help offset balance-of-payments imbalances.

As the United States encountered increasingly large balance-of-payments imbalances in the 1960s and early 1970s, its ability to maintain its gold peg of \$35 per ounce lost credibility. The United States abandoned the gold standard in 1971, thereby ending the Bretton Woods system. All major currencies then began the current regime of managed floating exchange rates.

The Economics of Developing Countries

Learning Objectives

- LO42.1** Describe how the World Bank distinguishes between industrially advanced countries and developing countries.
- LO42.2** List some of the obstacles to economic development.
- LO42.3** Explain the vicious circle of poverty that afflicts low-income nations.
- LO42.4** Discuss the role of government in promoting economic development within low-income nations.
- LO42.5** Describe how industrial nations attempt to aid low-income countries.

It is difficult for those of us in the United States, where per capita GDP in 2015 was about \$55,904, to grasp the fact that about 2.5 billion people, or nearly half the world's population, live on \$2 or less a day. And about 1.3 billion live on less than \$1.25 a day. Hunger, squalor, and disease are the norm in many nations of the world.

In this chapter we identify the developing countries, discuss their characteristics, and explore the obstacles that have impeded their growth. We also examine the appropriate roles of the private sector and government in economic development. Finally, we look at policies that might help developing countries increase their growth rates.

The Rich and the Poor

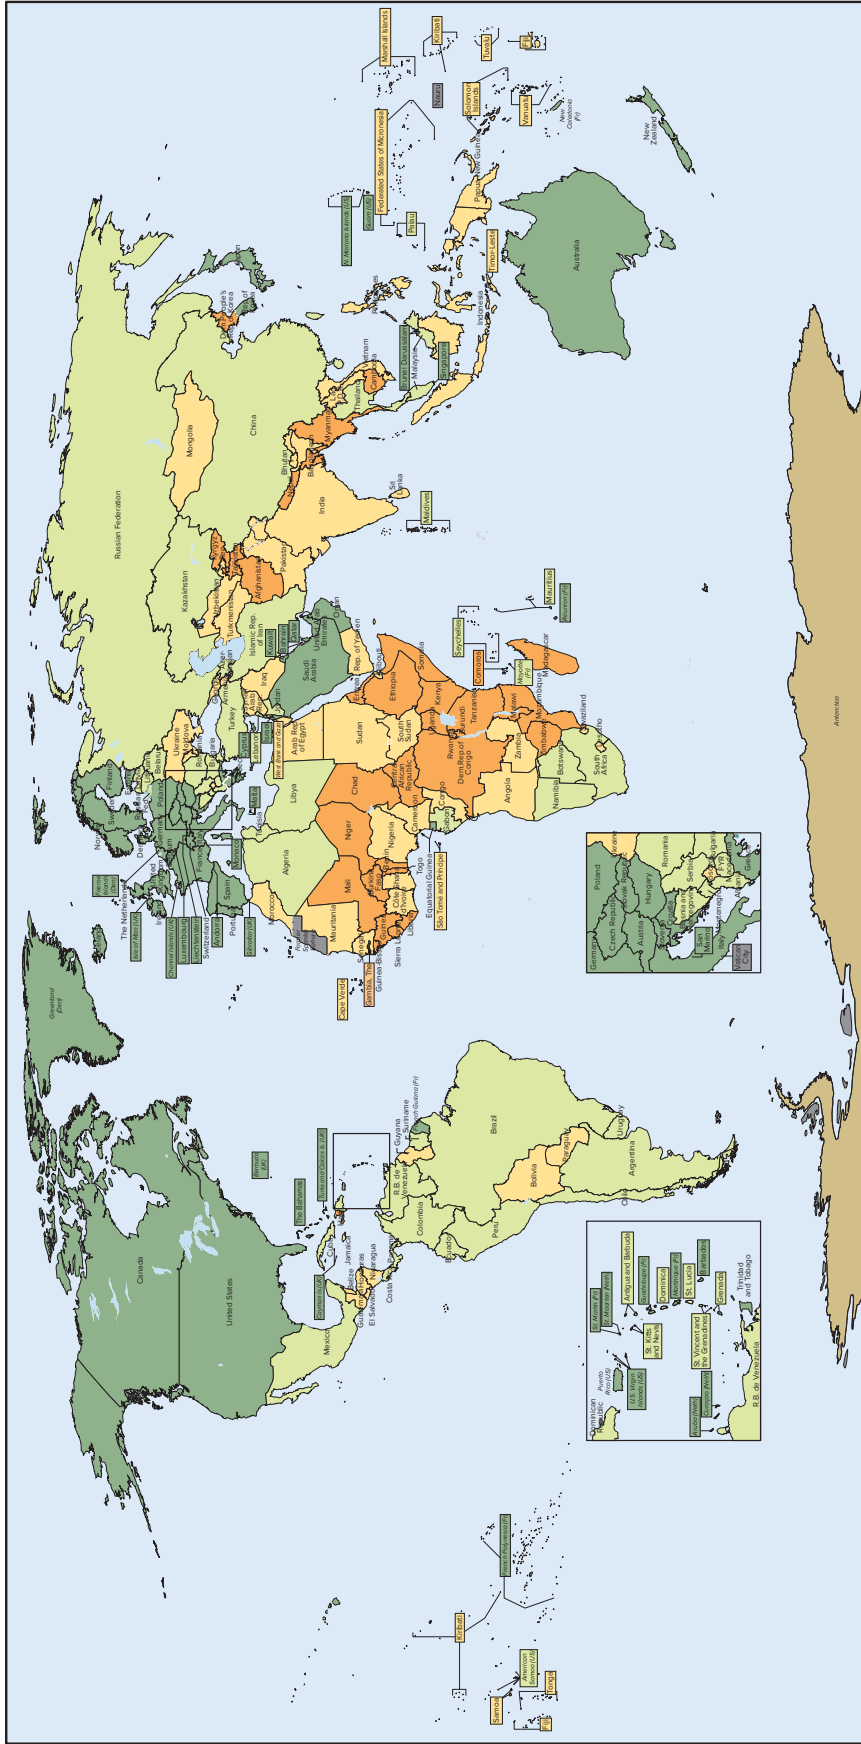

LO42.1 Describe how the World Bank distinguishes between industrially advanced countries and developing countries. Just as there is considerable income inequality among families within a nation, so too is there great income inequality among the family of nations. According to the United Nations, the richest 20 percent of the world's population receive more than 75 percent of the world's income; the poorest 20 percent receive less than 2 percent. The poorest 60 percent receive less than 6 percent of the world's income.

Classifications

The World Bank classifies countries into high-income, upper-middle-income, lower-middle-income, and low-income countries on the basis of national income per capita, as shown in Figure 42.1. The *high-income nations*, shown in dark green, are known as the **industrially advanced countries (IACs)**;

FIGURE 42.1 Groups of economies. The world's nations are grouped into industrially advanced countries (IACs) and developing countries (DVCs). The IACs (shown in dark green) are high-income countries. The DVCs are upper-middle-income, lower-middle-income, and low-income countries (shown respectively in light green, yellow, and orange).

they include the United States, Japan, Canada, Australia, New Zealand, and most of the nations of western Europe. In general, these nations have well-developed market economies based on large stocks of capital goods, advanced production technologies, and well-educated workers. In 2014 this group of economies had a per capita income of \$38,300.

The remaining nations of the world are called **developing countries (DVCs)**. They have wide variations of income per capita and are mainly located in Africa, Asia, and Latin America. The DVCs are a highly diverse group that can be subdivided into three groups:

- The *upper-middle-income nations*, shown in light green in Figure 42.1, include countries such as Brazil, Iran, South Africa, Mexico, China, and Thailand. The per capita output of these nations ranged all the way from \$4,126 to \$12,735 in 2014 and averaged \$7,926.
- The *lower-middle-income nations*, shown in yellow, had per capita incomes ranging from \$1,046 to \$4,125 in 2014 with an average per capita income of \$2,018. This category includes Armenia, India, Indonesia, Pakistan, Vietnam, and Zambia.
- The *low-income nations*, shown in orange, had a per capita income of \$1,045 or less in 2014 and averaged only \$628 of income per person. The sub-Saharan nations of Africa dominate this group. Low-income DVCs have relatively low levels of industrialization. In general, literacy rates are low, unemployment is high, population growth is rapid, and exports consist largely of agricultural produce (such as cocoa, bananas, sugar, raw cotton) and raw materials (such as copper, iron ore, natural rubber). Capital equipment is minimal, production technologies are simple, and labor productivity is very low. About 9 percent of the world's population live in these low-income DVCs, all of which suffer widespread poverty.

Comparisons

Several comparisons will bring the differences in world income into sharper focus:

- In 2014, U.S. GDP was \$17.3 trillion; the combined GDPs of the 135 DVCs in that year added up to \$25 trillion.
- The United States, with only 4.4 percent of the world's population in 2014, produced 22.3 percent of the world's output.
- Per capita GDP of the United States in 2014 was 70 times greater than per capita GDP in the Democratic Republic of the Congo, one of the world's poorest nations.
- The annual sales of the world's largest corporations exceed the national incomes of many of the DVCs. Walmart's annual world revenues of \$473 billion in 2014 were greater than the national incomes of all but 26 nations.

Growth, Decline, and Income Gaps

Two other points relating to the nations shown in Figure 42.1 should be noted. First, the various nations have demonstrated considerable differences in their ability to improve circumstances over time. On the one hand, DVCs such as Chile, China, India, Malaysia, and Thailand achieved high annual growth rates in their GDPs in recent decades. Consequently, their real output per capita increased severalfold. Several former DVCs, such as Singapore, Greece, and Hong Kong (now part of China), have achieved IAC status. In contrast, a number of DVCs in sub-Saharan Africa and the Middle East have recently been experiencing stagnant or even declining per capita GDPs.

Second, the absolute income gap between rich and poor nations has been widening. Suppose the per capita incomes of the advanced and developing countries were growing at about 2 percent per year. Because the income base in the advanced countries is initially much higher, the absolute income gap grows. If per capita income is \$400 a year in a DVC, a 2 percent growth rate means an \$8 increase in income. Where per capita income is \$20,000 per year in an IAC, the same 2 percent growth rate translates into a \$400 increase in income. Thus the absolute income gap will have increased from \$19,600 (= \$20,000 – \$400) to \$19,992 (= \$20,400 – \$408). The DVCs must grow faster than the IACs for the gap to be narrowed.

A quick glance back at Figure 28.1 in our chapter on economic growth will confirm the “great divergence” in standards of living that emerged by the end of the twentieth century between the United States, Western Europe, and Japan relative to Africa, Latin America, and Asia (excluding Japan).

The Human Realities of Poverty

Development economist Michael Todaro points out that mere statistics conceal the human implications of the extreme poverty in the low-income DVCs:

Let us examine a typical “extended” family in rural Asia. The Asian household is likely to comprise ten or more people, including parents, five to seven children, two grandparents, and some aunts and uncles. They have a combined annual income, both in money and in “kind” (i.e., they consume a share of the food they grow), of \$250 to \$300. Together they live in a poorly constructed one-room house as tenant farmers on a large agricultural estate ... The father, mother, uncle, and the older children must work all day on the land. None of the adults can read or write ... There is only one meal a day ... The house has no electricity, sanitation, or fresh water supply. There is much sickness, but qualified doctors and medical practitioners are far away in the cities attending to the needs of wealthier families. The work is hard, the sun is hot and aspirations for a better life are constantly being snuffed out. In this part of the world the only relief from the daily struggle for physical survival lies in the spiritual traditions of the people.¹

Obstacles to Economic Development

LO42.2 List some of the obstacles to economic development. The paths to economic development are essentially the same for developing countries and industrially advanced economies:

- The DVCs must use their existing supplies of resources more efficiently. This means that they must eliminate unemployment and underemployment and also combine labor and capital resources in a way that will achieve lowest-cost production. They must also direct their scarce resources so that they will achieve allocative efficiency.
- The DVCs must expand their available supplies of resources. By achieving greater supplies of raw materials, capital equipment, and productive labor, and by advancing its technological knowledge, a DVC can push its production possibilities curve outward.

All DVCs are aware of these two paths to economic development. Why, then, have some of them traveled those paths while others have lagged far behind? The difference lies in the physical, human, and socioeconomic environments of the various nations.

Natural Resources

No simple generalization is possible as to the role of natural resources in the economic development of DVCs

because the distribution of natural resources among them is so uneven. Some DVCs have valuable deposits of bauxite, tin, copper, tungsten, nitrates, and petroleum and have been able to use their natural resource endowments to achieve rapid growth. This is true, for instance, of Kuwait and several other members of the Organization of Petroleum Exporting Countries (OPEC). In other instances, natural resources are owned or controlled by the multinational corporations of industrially advanced countries, with the economic benefits from these resources largely diverted abroad. Furthermore, world markets for many of the farm products and raw materials that the DVCs export are subject to large price fluctuations that contribute to instability in their economies.

Other DVCs lack mineral deposits, have little arable land, and have few sources of power. Moreover, most of the poor countries are situated in Central and South America, Africa, the Indian subcontinent, and southeast Asia, where tropical climates prevail. The heat and humidity hinder productive labor; human, crop, and livestock diseases are widespread; and weed and insect infestations plague agriculture.

A weak resource base can be a serious obstacle to growth. Real capital can be accumulated and the quality of the labor force improved through education and training. But it is not as easy to augment the natural resource base. It may be unrealistic for many of the DVCs to envision an economic destiny comparable with that of, say, the United States or Canada. But we must be careful in generalizing: Japan, for example, has achieved a high standard of living despite limited natural resources. It simply imports the large quantities of natural resources that it needs to produce goods for consumption at home and export abroad.

Human Resources

Three statements describe many of the poorest DVCs with respect to human resources:

- Populations are large.
- Unemployment and underemployment are widespread.
- Educational levels and labor productivity are low.

Large Populations As demonstrated by equation (1), a nation's standard of living or real income per capita depends on the size of its total output (or income) relative to its total population:

$$\text{Standard of living} = \frac{\text{Total output (or income)}}{\text{Population}} \quad (1)$$

Some of the DVCs with the most meager natural and capital resources not only have low total incomes but also large populations. These large populations often produce high population densities (population per square mile). In column 2 of Table 42.2, note the high population densities of the selected DVCs relative to the lower densities of the United States and the world.

The high population densities of many DVCs have resulted from decades of higher rates of population growth than most IACs. Column 3 of Table 42.2 shows the varying rates of population growth in selected countries over a recent period: 2013–2014. Although *total fertility rates*—the number of children per woman's lifetime—are dramatically declining in most DVCs, the population growth rates of the DVCs remain considerably higher than for the IACs. Between 2000 and 2010, the annual population growth rate was 2.1 percent for the low-income DVCs and 1.2 percent for the middle-income DVCs. Those numbers compare to only a 0.7 percent

rate of population growth for the IACs. Because a large percentage of the world's current population already lives in DVCs, their population growth remains significant. Over the next 15 years, 9 out of every 10 people added to the world population are projected to be born in developing nations. Figure 42.2 dramatically illustrates the effect of population growth in the DVCs on past, present, and projected world population numbers. Population growth in the DVCs will continue to increase the world's population through midcentury, at which time world population is expected to begin to level off.

In some of the poorest DVCs, rapid population growth actually strains the levels of income growth so severely that per capita income remains stagnant or even falls toward subsistence levels. In the worst instances, death rates rise sharply as war, drought, and natural disasters cause severe malnutrition and disease.

Boosting the standard of living in countries that have subsistence or near-subsistence levels of income is a daunting task. When a DVC is just starting to modernize its economy, initial increases in real income can for a time increase population and short-circuit the process. If population increases are sufficiently large, they simply spread the higher level of total income among more people such that the original gain in per capita income disappears.

Why might income gains in the poorest DVC increase population growth, at least for a while? First, such income growth often reduces the nation's death rate. The increase in income means better nutrition and that improves health and

FIGURE 42.2 Population growth in developing countries and advanced industrial countries, 1950–2050. The majority of the world's population lives in the developing nations, and those nations will account for most of the increase in population through the middle of the twenty-first century.

increases life expectancy. Also, the death rate falls as a result of the basic medical and sanitation programs that accompany greater economic development. Second, the birthrate initially rises, particularly if medical and sanitation programs reduce infant mortality. For these reasons, the rapid population growth that results from income increases can convert an expanding standard of living into a stagnant or very-slow-growing standard of living.

Population expansion can also impede economic development in four additional ways:

- **Reduced saving and investment** The expenses associated with raising large families often reduce the capacity of households to save, thereby restricting the economy's ability to accumulate capital.
- **Lower productivity** As population increases, added investment is required to maintain the amount of real capital per person. If investment fails to keep pace, then on average each worker will have fewer tools and less equipment, and that will reduce worker productivity (output per worker). Declining productivity implies stagnating or declining per capita incomes.
- **Overuse of land resources** Because most developing countries are heavily dependent on agriculture, rapid population growth may cause an overuse of land resources. The much-publicized African famines of the 1980s and 1990s were partly the result of overgrazing and overplanting of land caused by the pressing need to feed a growing population. Population pressures also can encourage excessive cutting down of trees for use as fuel. This denuding of the landscape contributes to severe soil erosion from wind and water. Finally, in some cases population pressure leads to the use of crop waste and animal dung as needed fuel rather than as fertilizer to replenish the productivity of the soil.
- **Contribution to urban problems** Rapid population growth in the cities of the DVCs, accompanied by unprecedented inflows of rural migrants, generates massive urban problems. Rapid population growth aggravates problems such as substandard housing, poor public services, congestion, pollution, and crime. Resolving or reducing these difficulties necessitates diverting resources from growth-oriented uses.

Most authorities see birth control as a key strategy for breaking out of the population dilemma. And breakthroughs in contraceptive technology in recent decades have made this solution increasingly relevant. As we have indicated, fertility rates have dropped significantly in the DVCs. But obstacles to population control are still present. Low literacy rates make it difficult to disseminate information about contraceptive devices. In peasant agriculture, large families are a major source of labor. Adults may regard having many children as a

kind of informal social security system; the more children, the greater the probability of the parents' having a relative to care for them in old age.

Chinese authorities took a harsh stance on fertility choices in 1980, when they instituted a "one child per family" law that imposed fines, removed social benefits, and in some cases forced abortions on any family that had, or attempted to have, more than one child. The law was widely credited with assisting in the dramatic increase in living standards that accompanied China's subsequent economic boom. But the policy may have been too effective over the long run because, by 2015, China's labor force was declining and the government faced a situation in which too few workers would be paying taxes to support too many retirees. The law was overturned in late 2015 in hopes of encouraging Chinese families to have more children.

Qualifications We need to qualify our focus on population growth as a major cause of low per-capita incomes, however. As with the relationship between natural resources and living standards, the relationship between population sizes and living standards is less clear than one might expect. High population density certainly does not consign a nation to poverty. China and India have immense populations and are poor, but Japan, Singapore, and Hong Kong are densely populated and are wealthy. Moreover, the standard of living in many parts of China and India has rapidly increased in recent years.

Also, the population growth rate for the DVCs as a group has declined significantly in recent decades. Between 2000 and 2010, their annual population growth rate was about 1.3 percent; for 2010 through 2020, it is projected to fall to 1.1 percent (compared to 0.4 percent in the IACs). The world's population actually is projected to decline in the last part of this century.

Finally, not everyone agrees that reducing population growth is the best way to increase per capita GDP in the developing countries. Economists point to a **demographic transition** that occurs as economic growth takes off. In this transition, rising income transforms the population dynamics of a nation by reducing birthrates. In this view, high fertility rates and large populations are a consequence of low income, not the underlying cause. The task of a nation is to increase output and income. With success, declining birthrates will automatically follow.

This view recognizes both marginal benefits and marginal costs of having another child. In DVCs, the marginal benefits are relatively large because the extra child becomes an extra worker who can help support the family. Extra children can provide financial support and security for parents in their old age, so people in poor countries have high birthrates. But in wealthy IACs, the marginal cost of having another child is relatively high. Care of children may require that one of the parents incur the opportunity cost of sacrificing high earnings or that the parents purchase expensive child care. Also,

children require extended and expensive education for the highly skilled jobs characteristic of the IAC economies. At the same time, the marginal benefits of having a child may also be lower in a wealthy IAC. In particular, most IACs are wealthy enough to afford extensive “social safety nets” (such as retirement and disability benefits) that protect adults from the insecurity associated with old age and the inability to work. People in the IACs therefore recognize that high birthrates are not in the family’s short-term or long-term interest. Thus, many of them choose to have fewer children.

Note the differences in causation between the traditional view and the demographic transition view of population. The traditional view is that reduced birthrates must first be achieved and then higher per capita income can follow. Lower birthrates enable per capita income to rise. The demographic transition view is that higher output and income should first be achieved and then lower rates of population growth eventually will follow. Higher incomes reduce population growth.

Development economists typically suggest a dual approach to development that combines both views. The surest way for the poorest DVCs to break out of their poverty is to implement policies that expand output and income while establishing independent policies that give families greater access to birth control information and methods. In terms of the standard of living equation (1) earlier in this section, a set of policies that raises the numerator (total income) and holds constant or lowers the denominator (population) will provide the biggest lift to a developing nation’s standard of living.

Unemployment and Underemployment A second human resource dimension of developing countries relates to employment. For many DVCs, employment-related data are either nonexistent or highly unreliable. But observation suggests that unemployment is high. There is also significant **underemployment**, which means that a large number of people are employed fewer hours per week than they want, work at jobs unrelated to their training, or spend much of the time on their jobs unproductively.

Many economists contend that unemployment may be as high as 15 to 20 percent in the rapidly growing urban areas of the DVCs. There has been substantial migration in most developing countries from rural to urban areas, motivated by the expectation of finding jobs with higher wage rates than are available in agricultural and other rural employment. But this huge migration to the cities reduces a migrant’s chance of obtaining a job. In many cases, migration to the cities has greatly exceeded the growth of urban job opportunities, resulting in very high urban unemployment rates. Thus, rapid rural-urban migration has given rise to urban unemployment rates that are two or three times as great as rural rates.

Underemployment is widespread and characteristic of most DVCs. In many of the poorer DVCs, rural agricultural labor is so abundant relative to capital and natural resources

that a significant percentage of the labor contributes little or nothing to agricultural output. Similarly, many DVC workers are self-employed as proprietors of small shops, in handicrafts, or as street vendors. Unfortunately, however, many of them must endure long stretches of idle time at work due to a lack of demand. While they are not unemployed, they are clearly underemployed.

Low Labor Productivity The final human resource reality in developing nations is that labor productivity is low. As we will see, DVCs have found it difficult to invest in physical capital. As a result, their workers are poorly equipped with machinery and tools and therefore are relatively unproductive. Remember that rapid population growth tends to reduce the amount of physical capital available per worker, and that reduction erodes labor productivity and decreases real per capita incomes.

Moreover, most poor countries have not been able to invest adequately in their human capital (see Table 42.1, columns 3 and 4); consequently, expenditures on health and education have been meager. Low levels of literacy, malnutrition, lack of proper medical care, and insufficient educational facilities all contribute to populations that are ill equipped for industrialization and economic expansion. Attitudes may also play a role: In countries where hard work is associated with slavery and inferiority, many people try to avoid it. Also, by denying educational and work opportunities to women, many of the poorest DVCs forgo vast amounts of productive human capital.

Particularly vital is the absence of a vigorous entrepreneurial class willing to bear risks, accumulate capital, and provide the organizational requisites essential to economic growth. Closely related is the lack of labor trained to handle the routine supervisory functions basic to any program of development. Ironically, the higher-education systems of some DVCs emphasize the humanities and offer relatively few courses in business, engineering, and the sciences. Some DVCs are characterized by an authoritarian view of human relations, sometimes fostered by repressive governments, that creates an environment hostile to thinking independently, taking initiatives, and assuming economic risks. Authoritarianism discourages experimentation and change, which are the essence of entrepreneurship.

While migration from the DVCs has modestly offset rapid population growth, it has also deprived some DVCs of highly productive workers. Often the best-trained and most highly motivated workers, such as physicians, engineers, teachers, and nurses, leave the DVCs to better their circumstances in the IACs. This so-called **brain drain** contributes to the deterioration in the overall skill level and productivity of the labor force.

Capital Accumulation

The accumulation of capital goods is an important focal point of economic development. All DVCs have a relative dearth of

capital goods such as factories, machinery and equipment, and public utilities. Better-equipped labor forces would greatly enhance productivity and would help boost per capita output. There is a close relationship between output per worker (labor productivity) and real income per worker. A nation must produce more goods and services per worker as output to enjoy more goods and services per worker as income. One way of increasing labor productivity is to provide each worker with more tools and equipment.

Increasing the stock of capital goods is crucial because the possibility of augmenting the supply of arable land is slight. An alternative is to supply the available agricultural workforce with more and better capital equipment. And, once initiated, the process of capital accumulation may be cumulative. If capital accumulation increases output faster than the growth in population, a margin of saving may arise that permits further capital formation. In a sense, capital accumulation feeds on itself.

Let's first consider the possibility that developing nations will manage to accumulate capital domestically. Then we will consider the possibility that foreign funds will flow into developing nations to support capital expansion.

Domestic Capital Formation A developing nation, like any other nation, accumulates capital through saving and investing. A nation must save (refrain from consumption) to free some of its resources from the production of consumer goods. Investment spending must then absorb those released resources in the production of capital goods. But impediments to saving and investing are much greater in a low-income nation than they are in an advanced economy.

Savings Potential Consider first the savings side of the picture. The situation here is mixed and varies greatly between countries. Some of the very poor countries, such as Burundi, Chad, Ghana, Guinea, Liberia, Madagascar, Mozambique, and Sierra Leone, have negative saving or save only 0 to 7 percent of their GDPs. The people are simply too poor to save a significant portion of their incomes. Interestingly, however, some middle-income countries save a larger percentage of their domestic outputs than do advanced industrial countries. In 2010 India and China saved 34 and 53 percent of their domestic outputs, respectively, compared to 24 percent for Japan, 23 percent for Germany, and 11 percent for the United States. The problem is that the domestic outputs of the DVCs are so low that even when saving rates are larger than those of advanced nations, the total volume of saving is not large.

Capital Flight Some of the developing countries have suffered **capital flight**, the transfer of private DVC savings to accounts held in the IACs. (In this usage, "capital" is simply "money," "money capital," or "financial capital.") Many wealthy

citizens of DVCs have used their savings to invest in the more economically advanced nations, enabling them to avoid the high investment risks at home, such as loss of savings or real capital from government expropriation, abrupt changes in taxation, potential hyperinflation, or high volatility of exchange rates. If a DVC's political climate is unsettled, savers may shift their funds overseas to a "safe haven" in fear that a new government might confiscate their wealth. Rapid or skyrocketing inflation in a DVC would have similar detrimental effects. The transfer of savings overseas may also be a means of evading high domestic taxes on interest income or capital gains. Finally, money capital may flow to the IACs to achieve higher interest rates or a greater variety of investment opportunities.

Whatever the motivation, the amount of capital flight from some DVCs is significant and offsets much of the IACs' lending and granting of other financial aid to developing nations.

Investment Obstacles There are as many obstacles on the investment side of capital formation in DVCs as on the saving side. Those obstacles include a lack of investors and a lack of incentives to invest.

In some developing nations, the major obstacle to investment is the lack of entrepreneurs who are willing to assume the risks associated with investment. This is a special case of the human capital limitations of the labor force mentioned above.

But the incentive to invest may be weak even in the presence of substantial savings and a large number of willing entrepreneurs. Several factors may combine in a DVC to reduce investment incentives, including political instability, high rates of inflation, and lack of economies of scale. Similarly, very low incomes in a DVC result in a lack of buying power and thus weak demand for all but agricultural goods. This factor is crucial because the chances of competing successfully with mature industries in the international market are slim. Then, too, lack of trained administrative personnel may be a factor in retarding investment.

Finally, the **infrastructure** (stock of public capital goods) in many DVCs is insufficient to enable private firms to achieve adequate returns on their investments. Poor roads and bridges, inadequate railways, little gas and electricity production, poor communications, unsatisfactory housing, and inadequate educational and public health facilities create an inhospitable environment for private investment. A substantial portion of any new private investment would have to be used to create the infrastructure needed by all firms. Rarely can firms provide an investment in infrastructure themselves and still earn a positive return on their overall investment.

For all these reasons, investment incentives in many DVCs are lacking. It is significant that four-fifths of the overseas investments of multinational firms go to the IACs and only one-fifth to the DVCs. If the multinationals are reluctant

to invest in the DVCs, we can hardly blame local entrepreneurs for being reluctant too.

How then can developing nations build up the infrastructure needed to attract investment? The higher-income DVCs may be able to accomplish this through taxation and public spending. But, in the poorest DVCs, there is little income to tax. Nevertheless, with leadership and a willingness to cooperate, a poor DVC can accumulate capital by transferring surplus agricultural labor to the improvement of the infrastructure. If each agricultural village allocated its surplus labor to the construction of irrigation canals, wells, schools, sanitary facilities, and roads, significant amounts of capital might be accumulated at no significant sacrifice of consumer goods production. Such investment bypasses the problems inherent in the financial aspects of the capital accumulation process. It does not require that consumers save portions of their money income, nor does it presume the presence of an entrepreneurial class eager to invest. When leadership and cooperative spirit are present, this “in-kind” investment is a promising avenue for accumulation of basic capital goods.

Technological Advance

Technological advance and capital formation are frequently part of the same process. Yet there are advantages in discussing technological advance separately.

Given the rudimentary state of technology in the DVCs, they are far from the frontiers of technological advance. But the IACs have accumulated an enormous body of technological knowledge that the developing countries might adopt and apply without expensive research. Crop rotation and contour plowing require no additional capital equipment and would contribute significantly to productivity. By raising grain storage bins a few inches above ground, a large amount of grain spoilage could be avoided. Although such changes may sound trivial to people of advanced nations, the resulting gains in productivity might mean the difference between subsistence and starvation in some poverty-ridden nations.

The application of either existing or new technological knowledge often requires the use of new and different capital goods. But, within limits, a nation can obtain at least part of that capital without an increase in the rate of capital formation. If a DVC channels the annual flow of replacement investment from technologically inferior to technologically superior capital equipment, it can increase productivity even with a constant level of investment spending. Actually, it can achieve some advances through **capital-saving technology** rather than **capital-using technology**. A new fertilizer, better adapted to a nation’s topography and climate, might be cheaper than the fertilizer currently being used. A seemingly high-priced metal plow that will last 10 years may be cheaper in the long run than an inexpensive but technologically inferior wooden plow that has to be replaced every year.

To what extent have DVCs adopted and effectively used available IAC technological knowledge? The picture is mixed. There is no doubt that such technological borrowing has been instrumental in the rapid growth of such Pacific Rim countries as Japan, South Korea, Taiwan, and Singapore. Similarly, the OPEC nations have benefited significantly from IAC knowledge of oil exploration, production, and refining. Recently Russia, the nations of eastern Europe, and China have adopted Western technology to hasten their conversion to market-based economies.

Still, the transfer of advanced technologies to the poorest DVCs is not an easy matter. In IACs technological advances usually depend on the availability of highly skilled labor and abundant capital. Such advances tend to be capital-using or, to put it another way, labor-saving. Developing economies require technologies appropriate to quite different resource endowments: abundant unskilled labor and very limited quantities of capital goods. Although labor-using and capital-saving technologies are appropriate to DVCs, much of the highly advanced technology of advanced nations is inappropriate to them. They must develop their own appropriate technologies. Moreover, many DVCs have “traditional economies” and are not highly receptive to change. That is particularly true of peasant agriculture, which dominates the economies of most of the poorer DVCs. Since technological change that fails may well mean hunger and malnutrition, there is a strong tendency to retain traditional production techniques.

Sociocultural and Institutional Factors

Economic considerations alone do not explain why an economy does or does not grow. Substantial sociocultural and institutional readjustments are usually an integral part of the growth process. Economic development means not only changes in a nation’s physical environment (new transportation and communications facilities, new schools, new housing, new plants and equipment) but also changes in the way people think, behave, and associate with one another. Emancipation from custom and tradition is frequently a prerequisite of economic development. A critical but intangible ingredient in that development is the **will to develop**. Economic growth may hinge on what individuals within DVCs want for themselves and their children. Do they want more material abundance? If so, are they willing to make the necessary changes in their institutions and old ways of doing things?

Sociocultural Obstacles Sociocultural impediments to growth are numerous and varied. Some of the very-low-income countries have failed to achieve the preconditions for a national economic entity. Tribal and ethnic allegiances take precedence over national allegiance. Each tribe confines its economic activity to the tribal unit, eliminating any possibility for production-increasing specialization and trade.

The desperate economic circumstances in Somalia, Sudan, Libya, Syria, and Afghanistan are due in no small measure to military and political conflicts among rival groups.

In countries with a formal or informal caste system, labor is allocated to occupations on the basis of status or tradition rather than on the basis of skill or merit. The result is a misallocation of human resources.

Religious beliefs and observances may seriously restrict the length of the workday and divert to ceremonial uses resources that might have been used for investment. Some religious and philosophical beliefs are dominated by the fatalistic view that the universe is capricious, the idea that there is little or no correlation between an individual's activities and endeavors and the outcomes or experiences that person encounters. The **capricious-universe view** leads to a fatalistic attitude. If "providence" rather than hard work, saving, and investing is the cause of one's lot in life, why save, work hard, and invest? Why engage in family planning? Why innovate?

Other attitudes and cultural factors may impede economic activity and growth: emphasis on the performance of duties rather than on individual initiative; focus on the group rather than on individual achievement; and the belief in reincarnation, which reduces the importance of one's current life.

Institutional Obstacles Political corruption and bribery are common in many DVCs. School systems and public service agencies are often ineptly administered, and their functioning is frequently impaired by petty politics. Tax systems are frequently arbitrary, unjust, cumbersome, and detrimental to incentives to work and invest. Political decisions are often motivated by a desire to enhance the nation's international prestige rather than to foster development.

Because of the predominance of farming in DVCs, the problem of achieving an optimal institutional environment in agriculture is a vital consideration in any growth program. Specifically, the institutional problem of **land reform** demands attention in many DVCs. But the reform that is needed may vary tremendously from nation to nation. In some DVCs the problem is excessive concentration of land ownership in the hands of a few wealthy families. This situation is demoralizing for tenants, weakens their incentive to produce, and typically does not promote capital improvements. At the other extreme is the situation in which each family owns and farms a piece of land far too small for the use of modern agricultural technology. An important complication to the problem of land reform is that political considerations sometimes push reform in the direction of farms that are too small to achieve economies of scale. For many nations, land reform is the most acute institutional problem to be resolved in initiating economic development.

Examples: Land reform in South Korea weakened the political control of the landed aristocracy and opened the way for the emergence of strong commercial and industrial middle

classes, all to the benefit of the country's economic development. In contrast, the prolonged dominance of the landed aristocracy in the Philippines may have stifled economic development in that nation.

QUICK REVIEW 42.1

- ✓ About 9 percent of the world's population lives in the low-income DVCs, which typically are characterized by scarce natural resources, inhospitable climates, large populations, high unemployment and underemployment, low education levels, and low labor productivity.
- ✓ For DVCs just beginning to modernize, high birthrates caused by improved medical care and sanitation can increase population faster than income growth, leading to lower living standards; but as development continues, the opportunity costs of having children rise and population growth typically slows.
- ✓ Low saving rates, capital flight, weak infrastructures, and lack of investors impair capital accumulation in many DVCs.
- ✓ Sociocultural and institutional factors are often serious impediments to economic growth in DVCs.

The Vicious Circle

L042.3 Explain the vicious circle of poverty that afflicts low-income nations.

Many of the characteristics of the poorest of the DVCs just described are both causes and consequences of their poverty. These countries are caught in a **vicious circle of poverty**. They stay poor because they are poor! Consider Figure 42.3. Common to most DVCs is low per capita income. A family that is poor has little ability or incentive to save. Furthermore, low incomes mean low levels of product demand. Thus, there are few available resources, on the one hand, and no strong incentives, on the other hand, for investment in physical or human capital. Consequently, labor productivity is low. And since output per person is real income per person, it follows that per capita income is low.

Many economists think that the key to breaking out of this vicious circle is to increase the rate of capital accumulation, to achieve a level of investment of, say, 10 percent of the national income. But Figure 42.3 reminds us that rapid population growth may partially or entirely undo the potentially beneficial effects of a higher rate of capital accumulation. Suppose that initially a DVC is realizing no growth in its real GDP but somehow manages to increase saving and investment to 10 percent of its GDP. As a result, real GDP begins to grow at, say, 2.5 percent per year. With a stable population, real GDP per capita will also grow at 2.5 percent per year. If that growth persists, the standard of living will double in

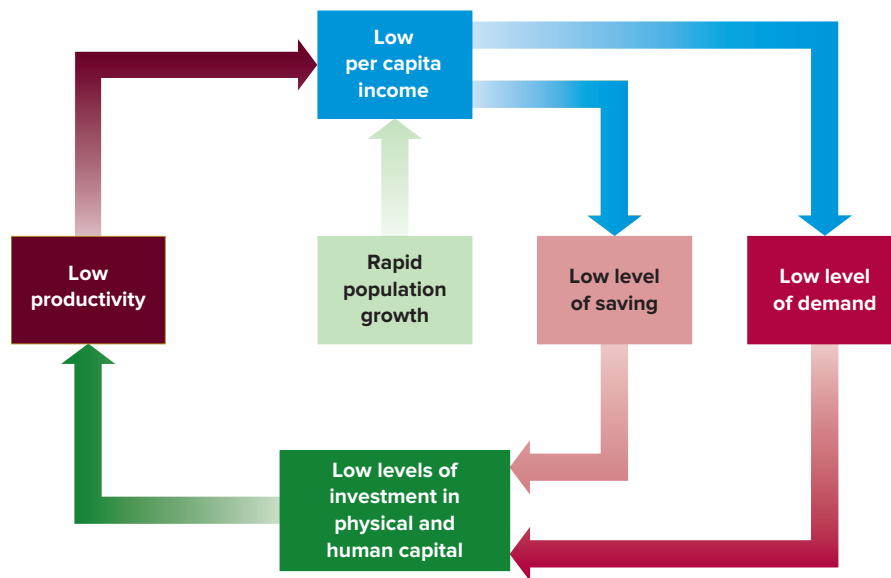

FIGURE 42.3 The vicious circle of poverty. Low per capita incomes make it difficult for poor nations to save and invest, a condition that perpetuates low productivity and low incomes. Furthermore, rapid population growth may quickly absorb increases in per capita real income and thereby destroy the possibility of breaking out of the poverty circle.

about 28 years. But what if population also grows at the rate of 2.5 percent per year, as it does in parts of the Middle East, northern Africa, and sub-Saharan Africa? Then real income per person will remain unchanged and the vicious circle will persist.

But if population can be kept constant or limited to some growth rate significantly below 2.5 percent, real income per person will rise. Then the possibility arises of further enlargement of the flows of saving and investment, continuing advances in productivity, and the continued growth of per capita real income. If a process of self-sustaining expansion of income, saving, investment, and productivity can be achieved, the self-perpetuating vicious circle of poverty can be transformed into a self-regenerating, beneficent circle of economic progress. The challenge is to make effective policies and strategies that will accomplish that transition.

The Role of Government

LO42.4 Discuss the role of government in promoting economic development within low-income nations.

Economists see a positive role for government in fostering DVC growth, but they generally agree that government efforts must support private efforts, not substitute for them. That is not always the case in practice.

A Positive Role

Economists suggest that developing nations have several avenues for fostering economic growth and improving their standards of living.

Establishing the Rule of Law Some of the poorest countries of the world are plagued by banditry and intertribal warfare

that divert attention and resources from the task of development. A strong, stable national government is needed to establish domestic law and order and to achieve peace and unity. Research demonstrates that political instability (as measured by the number of revolutions and coups per decade) and slow economic growth go hand in hand.

Clearly defined and strictly enforced property rights bolster economic growth by ensuring that individuals receive and retain the fruits of their labor. Because legal protections reduce investment risk, the rule of law encourages direct investments by firms in the IACs. Government itself must live by the law. The presence of corruption in the government sanctions criminality throughout the economic system. Such criminality discourages the growth of output because it lowers the returns available to honest workers and honest businesspeople.

Building Infrastructure Many obstacles to economic growth are related to an inadequate infrastructure. Sanitation and basic medical programs, education, irrigation and soil conservation projects, and construction of transportation links and communication facilities are all essentially nonmarketable goods and services that yield widespread spillover benefits. Government is the only institution that is in a position to provide public infrastructure. But it need not do all the work through government entities. It can contract out much of the work to private enterprises.

With respect to both private and public infrastructure, DVCs have an unexpected advantage over more developed countries because they can act as *follower countries* when it comes to technology. As explained in Chapter 28 on economic growth, DVCs can simply adopt technologies that were developed at high cost in the more technologically

advanced *leader countries* without having to pay any of the development costs of those technologies. DVCs can often jump directly to the most modern and highly productive infrastructure without going through the long process of development and replacement that was required in the IACs. As a good example, many DVCs have developed Internet-capable wireless phone networks instead of using their scarce resources to build and expand landline systems.

Embracing Globalization Other things equal, open economies that participate in international trade grow faster than closed economies. Also, DVCs that welcome foreign direct investment enjoy greater growth rates than DVCs that view such investment suspiciously or even as exploitation and therefore put severe obstacles in its way.

Realistic exchange-rate policies by government also help. Exchange rates that are fixed at unrealistic levels invite balance-of-payments problems and speculative trading in currencies. Often, such trading forces a nation into an abrupt devaluation of its currency, sending shock waves throughout its economy. More flexible exchange rates enable more gradual adjustments and thus less susceptibility to major currency shocks and the domestic disruption they cause.

Building Human Capital Government programs that encourage literacy, education, and labor market skills enhance economic growth by building human capital. In particular, policies that close the education gap between women and men spur economic growth in developing countries. Promoting the education of women pays off in terms of reduced fertility, greater productivity, and greater emphasis on educating children.

And government is in a position to nurture the will to develop, to change a philosophy of “Heaven and faith will determine the course of events” to one of “God helps those who help themselves.” That change encourages personal educational attainment and enhanced human capital.

Promoting Entrepreneurship The lack of a sizable and vigorous entrepreneurial class, ready and willing to accumulate capital and initiate production, indicates that in some DVCs, private enterprise is not capable of spearheading the growth process. Government may have to take the lead, at least at first. But many DVCs would benefit by converting some of their state enterprises into private firms. State enterprises often are inefficient, more concerned with providing maximum employment than with introducing modern technology and delivering goods and services at minimum per-unit cost. Moreover, state enterprises are poor “incubators” for developing profit-focused, entrepreneurial persons who leave the firm to set up their own businesses.

Developing Credit Systems The banking systems in some of the poorest DVCs are nearly nonexistent and that

makes it difficult for domestic savers and international lenders to lend money to DVC borrowers, who in turn wish to create capital goods. An effective first step in developing credit systems is through **microcredit**, in which groups of people pool their money and make small loans to budding entrepreneurs and owners of small businesses. People from the IACs can do the same, helping nurture the spirit of enterprise and foster the benefits that it brings. The benefits of microlending accrue not only to the entrepreneurs in the DVCs but to the country as a whole because the lending creates jobs, expands output, and raises the standard of living.

At the national level, DVC governments must guard against excessive money creation and the high inflation that it brings. High rates of inflation simply are not conducive to economic investment and growth because inflation lowers the real returns generated by investments. DVCs can help keep inflation in check by establishing independent central banks to maintain proper control over their money supplies. Studies indicate that DVCs that control inflation enjoy higher growth rates than those that do not.

Controlling Population Growth Government can provide information about birth control options. We have seen that slower population growth can convert increases in real output and income to increases in real *per capita* output and income. Families with fewer children consume less and save more; they also free up time for women for education and participation in the labor market. As women participate in the labor market, they tend to reduce their fertility rate, which further helps to control population growth.

Making Peace with Neighbors Countries at war or in fear of war with neighboring nations divert scarce resources to armaments, rather than to private capital or public infrastructure. Sustained peace among neighboring nations eventually leads to economic cooperation and integration, broadened markets, and stronger economic growth.

Public-Sector Problems

Although the public sector can positively influence economic development, serious problems can and do arise with government-directed initiatives. If entrepreneurial talent is lacking in the private sector, are quality leaders likely to surface in the ranks of government? Is there not a real danger that government bureaucracy will impede, not stimulate, social and economic change? And what of the tendency of some political leaders to favor spectacular “showpiece” projects at the expense of less showy but more productive programs? Might not political objectives take precedence over the economic goals of a governmentally directed development program?

Development experts are less enthusiastic about the role of government in the growth process than they were 30 years

The Corruption Perceptions Index, Selected Nations, 2015*

The corruption perceptions index measures the degree of corruption existing among public officials and politicians as seen by business people, risk analysts, and the general public. An index value of 100 is highly clean and 0 is highly corrupt.

ago. Unfortunately, government misadministration and **corruption** are common in many DVCs, and government officials sometimes line their own pockets with foreign-aid funds. Moreover, political leaders often confer monopoly privileges on relatives, friends, and political supporters and grant exclusive rights to relatives or friends to produce, import, or export certain products. Such monopoly privileges lead to higher domestic prices and diminish the DVC's ability to compete in world markets.

Similarly, managers of state-owned enterprises are often appointed on the basis of cronyism rather than competence. Many DVC governments, particularly in Africa, have created "marketing boards" as the sole purchaser of agricultural products from local farmers. The boards buy farm products at artificially low prices and sell them at higher world prices; the "profit" ends up in the pockets of government officials. In recent years the perception of government has shifted from that of catalyst and promoter of growth to that of a potential

impediment to development. According to a recent ranking of 176 nations based on perceived corruption, the 40 nations at the bottom of the list (most corrupt) were DVCs. Global Perspective 42.1 shows the corruption scores for 16 selected nations, including the two least corrupt (Denmark and Singapore) and the two most corrupt (Afghanistan and Somalia).

The Role of Advanced Nations

L042.5 Describe how industrial nations attempt to aid low-income countries.

How can the IACs help developing countries in their pursuit of economic growth? To what degree have IACs provided assistance?

Expanding Trade

Some authorities maintain that the simplest and most effective way for the United States and other industrially advanced nations to aid developing nations is to lower international trade barriers. Such action would enable DVCs to elevate their national incomes through increased trade. Trade barriers instituted by the IACs are often highest for labor-intensive manufactured goods, such as textiles, clothing, footwear, and processed agricultural products. These are precisely the sorts of products for which the DVCs have a comparative advantage. Also, many IACs' tariffs rise as the degree of product processing increases; for example, tariffs on chocolates are higher than those on cocoa. This practice discourages the DVCs from developing processing industries of their own.

Additionally, large agricultural subsidies in the IACs encourage excessive production of food and fiber in the IACs. The overproduction flows into world markets, where it depresses agricultural prices. DVCs, which typically do not subsidize farmers, therefore face artificially low prices for their farm exports. The IACs could greatly help DVCs by reducing farm subsidies along with tariffs.

But lowering trade barriers is certainly not a panacea. Some poor nations need only large foreign markets for their raw materials to achieve growth. But the problem for many poor nations is not to obtain markets in which to sell existing products or relatively abundant raw materials but to get the capital and technical assistance they need to produce products for domestic consumption.

Also, close trade ties with advanced nations entail certain disadvantages. Dependence by the DVCs on exports to the IACs leaves the DVCs highly vulnerable to recessions in the IACs. As firms cut back production in the IACs, the demand for DVC resources declines; and as income in the IACs declines, the demand for DVC-produced goods declines. By reducing the demand for DVC exports, recessions in the IACs can severely reduce the prices of raw materials exported by the DVCs. For example, during the recession of 2007–2009,

the world price of zinc fell from \$2.02 per pound to \$0.49 per pound, and the world price of copper fell from \$4.05 per pound to \$1.40 per pound. These declines in prices severely reduce the export earnings of the DVCs. Because mineral exports are a significant source of DVC income, stability and growth in IACs are important to improved standards of living in the developing nations.

Admitting Temporary Workers

Some economists recommend that the IACs help the DVCs by accepting more seasonal or other temporary workers from the DVCs. Temporary migration provides an outlet for surplus DVC labor. Moreover, migrant remittances to families in the home country serve as a sorely needed source of income. The problem, of course, is that some temporary workers illegally blend into the fabric of the IACs and do not leave when their visas or work permits expire. That may not be in the long-run best interest of the IACs.

Discouraging Arms Sales

Finally, the IACs can help the DVCs as a group by discouraging the sale of military equipment to the DVCs. Such purchases by the DVCs divert public expenditures from infrastructure and education and heighten tensions in DVCs that have long-standing disputes with neighbors.

Foreign Aid: Public Loans and Grants

Official development assistance (ODA), or simply “foreign aid,” is another route through which IACs can help DVCs. This aid can play a crucial role in breaking an emerging country’s circle of poverty by supplementing its saving and investment. As previously noted, many DVCs lack the infrastructure needed to attract either domestic or foreign private capital. The infusion of foreign aid that strengthens infrastructure could enhance the flow of private capital to the DVCs.

Direct Aid The United States and other IACs have assisted DVCs directly through a variety of programs designed to stimulate economic development. Over the past 10 years, U.S. loans and grants to the DVCs totaled \$20 billion to \$31 billion per year. The U.S. Agency for International Development (USAID) administers most of this aid. Some of it, however, consists of grants of surplus food under the Food for Peace program. Other advanced nations also have substantial foreign aid programs. In 2015 foreign aid from the IACs to the developing nations totaled \$132 billion. This amounted to about one-fourth of 1 percent of the collective GDP of the IACs that year (see Global Perspective 42.2 for percentages for selected nations).

A large portion of foreign aid is distributed on the basis of political and military rather than strictly economic considerations. Afghanistan, Egypt, Iraq, Israel, Pakistan, and Turkey,

for example, are major recipients of U.S. aid. Asian, Latin American, and African nations with lower standards of living receive less.

Only one-fourth of foreign aid goes to the 10 countries in which 70 percent of the world’s poorest people live. The most affluent 40 percent of the DVC population receives over twice as much aid as the poorest 40 percent. Many economists argue that the IACs should shift foreign aid away from the middle-income DVCs and toward the poorest DVCs.

Some of the world’s poorest nations *do* receive large amounts of foreign aid relative to their meager GDPs. For example, in 2014 foreign aid relative to GDP was 63 percent in Tuvalu, 44 percent in Liberia, 23 percent in Afghanistan, 21 percent in Sierra Leone, and 13 percent in Mozambique.

Also, these and many other low-income developing nations receive large amounts of support from private donors in the IACs. In fact, in recent years the private giving to the DVCs by private U.S. universities, foundations (such as the Gates Foundation), voluntary organizations, and religious organizations has exceeded the foreign aid provided by the U.S. government.

The large accumulated debts of some of the poorest DVCs have become a severe roadblock to their growth. Therefore,

some of the recent direct assistance by the IACs to the DVCs has taken the form of forgiving parts of the past IAC-government loans to low-income DVCs. In 2005 the G8 nations canceled \$55 billion of debt owed by developing countries to the World Bank, the International Monetary Fund, and the African Development Bank. Of course, debt forgiveness creates a *moral hazard problem*. If current debt forgiveness creates an expectation of later debt forgiveness, a country has little incentive against running up a new debt. Therefore, future loans by the IACs must be extended cautiously to the low-income developing nations that receive current debt forgiveness.

The World Bank Group The United States and other IACs also support the DVCs by participating in the **World Bank**, whose major objective is helping DVCs achieve economic growth. The World Bank was established in 1945, along with the International Monetary Fund (IMF). Supported by about 188 member nations, the World Bank not only lends out of its capital funds but also sells bonds and lends the proceeds and guarantees and insures private loans:

- The World Bank is a “last-resort” lending agency; its loans are limited to economic projects for which private funds are not readily available.
- Many World Bank loans have been for basic development projects—dams, irrigation projects, health and sanitation programs, communications, and transportation facilities. Consequently, the Bank has helped finance the infrastructure needed to encourage the flow of private capital.
- The Bank has provided technical assistance to the DVCs by helping them determine what avenues of growth seem appropriate for their economic development.

Affiliates of the World Bank function in areas where the World Bank has proved weak. The *International Finance Corporation (IFC)*, for example, invests in private enterprises in the DVCs. The *International Development Association (IDA)* makes “soft loans” (which may not be self-liquidating) to the poorest DVCs on more liberal terms than does the World Bank.

Foreign Harm? Although official development assistance directly from the IACs and indirectly through the World Bank has generally helped the DVCs expand their economies, the foreign-aid approach to helping DVCs has met with several criticisms.

Dependency and Incentives A basic criticism is that foreign aid may promote dependency rather than self-sustaining growth. Critics argue that injections of funds from the IACs encourage the DVCs to ignore the painful economic decisions, the institutional and cultural reforms, and the changes in attitudes toward thrift, industry, hard work, and self-reliance that

are needed for economic growth. They say that, after some five decades of foreign aid, the DVCs’ demand for foreign aid has increased rather than decreased. These aid programs should have withered away if they had been successful in promoting sustainable growth.

Bureaucracy and Centralized Government IAC aid is given to the governments of the DVCs, not to their residents or businesses. The consequence is that the aid typically generates massive, ineffective government bureaucracies and centralizes government power over the economy. The stagnation and collapse of the Soviet Union and communist countries of eastern Europe is evidence that highly bureaucratized economies are not very conducive to economic growth and development. Furthermore, not only does the bureaucratization of the DVCs divert valuable human resources from the private to the public sector, but it often shifts the nation’s focus from producing more output to bickering over how unearned “income” should be distributed.

Corruption and Misuse Critics also allege that foreign aid is being used ineffectively. As we noted previously, corruption is a major problem in many DVCs, and some estimates suggest that from 10 to 20 percent of the aid is diverted to government officials. Also, IAC-based aid consultants and multinational corporations are major beneficiaries of aid programs. Some economists contend that as much as one-fourth of each year’s aid is spent on expert consultants. Furthermore, because IAC corporations manage many of the aid projects, they are major beneficiaries of, and lobbyists for, foreign aid.

Current Level of Foreign Aid After declining in the late 1990s, foreign aid increased between 2000 and 2008. This increase resulted from a renewed international emphasis on reducing global poverty and also from expanded efforts by the IACs to enlist the cooperation of DVCs in fighting terrorism. In 2015 foreign direct aid by IAC governments to developing countries was \$132 billion.

Flows of Private Capital

The IACs also send substantial amounts of private capital to the DVCs. Among the private investors are corporations, commercial banks, and, more recently, financial investment companies. General Motors or Ford might finance the construction of plants in Mexico or Brazil to assemble autos or produce auto parts. JPMorgan Chase or Bank of America might make loans to private firms operating in Argentina or China or to the governments of Thailand and Malaysia. And individuals living in IACs might purchase shares in “emerging markets” mutual funds run by investment companies like Fidelity. Those funds make financial investments in the stock of promising firms in DVCs such as Hungary and Chile.

The total flow of private capital to DVCs was \$172 billion in 2014, but the makeup of this flow differed from the

Microfinance and Cash Transfers

Development Efforts Have Increasingly Focused on Lending, Granting, or Gifting Money to Individuals.

For the most of the twentieth century, international development efforts focused on infrastructure projects, such as building roads, bridges, and electrical grids. Efforts aimed directly at individuals were relatively rare and poorly funded. That has changed drastically in the last few decades as development efforts have become increasingly focused on delivering cash directly to poor individuals. The results, however, have been mixed.

Microcredit In the mid-1970s, a Bangladeshi economics professor named Muhammad Yunus discovered that making small loans to poor villagers in his native Bangladesh could sometimes facilitate economic growth and advancement at the individual level. A group of women could, for instance, start a modest but profitable textile company if they could borrow amounts of money as small as \$10 or \$20 to purchase looms and other equipment.

The even more startling part was that these small loans, or **microcredit**, were nearly always paid back. Whereas the poor had often been thought of by development experts as being too uneducated or inexperienced to help themselves out of poverty, Yunus showed that the poor often had good business sense and were in some cases constrained not by ignorance but by a lack of capital.

In 1983, Yunus established the Grameen Bank (literally the “Village Bank”) to provide microcredit throughout Bangladesh. The

Grameen Bank later expanded beyond microcredit into banking and insurance services for the poor, a set of activities that came to be referred to as **microfinance**. Its individual-focused approach to development spawned hundreds of imitators in scores of nations and earned Yunus the 2006 Nobel Peace Prize.

Unfortunately, development economists have found that microfinance does not offer a consistent way out of poverty by itself.

flow in earlier decades. The main private investors and lenders are now private IAC firms and individuals, not commercial banks. Also, more of the flow is in the form of **foreign direct investment** in DVCs, rather than loans to DVC governments. Such direct investment includes the building of new factories in DVCs by multinational firms and the purchase of DVC firms (or parts of them). Whereas DVCs once viewed foreign direct investment as “exploitation,” many of them now seek out foreign direct investment as a way to expand their capital stock and improve their citizens’ job opportunities and wages. Those wages are often very low by IAC standards but high by DVC standards. Another benefit of direct investment in DVCs is that management skills and technological knowledge often accompany the capital.

Unfortunately for the low-income DVCs, the strong flow of private capital to the DVCs has been very selective. The vast majority of IAC investment and lending has been directed toward China, India, Mexico, and other middle-income DVCs, with only small amounts flowing toward such extremely impoverished DVCs as those in Africa.

In fact, as we have indicated, many of the lowest-income countries face staggering debt burdens from previous government and private loans. Payment of interest and principal on this external debt is diverting expenditures away from maintenance of infrastructure, new infrastructure, education, and private investment.

Further, the flows of private capital to both the middle-income and low-income DVCs plummeted after the worldwide recession of 2007–2009. It may be several years before foreign direct investment regains its momentum.

QUICK REVIEW 42.2

- ✓ The IACs can assist the DVCs through expanded trade, foreign aid, and flows of private capital.
- ✓ Many of the poorest DVCs have large external debts that pose an additional obstacle to economic growth.
- ✓ The worldwide recession of 2007–2009 greatly reduced direct investment by the IACs in the DVC economies.

Randomized experiments show that, on average, the households and individuals receiving microcredit usually do no better than non-recipients on economic, health, and social outcomes such as family income, the total number of calories consumed, and rates of school attendance.

Conditional Cash Transfers Conditional cash transfer programs provide poor families with transfers (grants) of cash if they send their children to school and participate in preventative health programs. As just one example, the Mexican government's *Oportunidades* program gives bi-weekly cash grants to poor families who keep their kids in school and participate in health screenings and nutritional programs.

Conditional cash transfer programs have been in place since the early 1990s, which makes them old enough for us to be able to draw some conclusions about their effectiveness. Some very positive outcomes are apparent. The programs have been shown to increase school enrollment by up to 30 percent and to improve health and nutrition so much that rates of illness among young children fall by more than 10 percent. Children enrolled in conditional cash transfer programs also end up taller than children who are not enrolled.

Unfortunately, the effectiveness of conditional cash transfers in relieving poverty in developing countries is limited by other factors. As just one example, school enrollment goes up but test scores stay the same, probably because the schools themselves are poorly funded and often ineffective. Similarly, the wages earned by the students who stay in school longer don't seem to be much higher than those of the students who dropped out earlier, probably because of the low quality of many schools as well as high rates of unemployment in many local labor markets.

Unconditional Cash Transfers The newest antipoverty initiatives targeted at individuals are known as **unconditional cash transfers** because they simply hand cash to poor adults with no conditions attached. They operate under the theory that many poor people are held back by a lack of either physical or human capital, and that if you were to give them no-strings-attached cash, they would use the money to pay for tools and training.

That assumption has proven true in early testing. As an example, a randomized study in Uganda that started in 2008 offered the chance to receive unconditional cash transfers to young people who were willing to submit essays detailing what they planned to do with any money received. Half of the participants were then randomly selected to receive the money, with it being made explicitly clear that nobody would be following up to see if the recipients actually spent the money on what they had written in their essays (which, for the most part, indicated a desire to spend cash transfers on vocational training and business equipment).

The researchers running the study found that the half who were randomly selected to receive unconditional cash transfers ended up "65 percent more likely to practice a skilled trade such as carpentry, metalworking, tailoring, or hairstyling" than those who did not receive unconditional cash transfers. Even better, the results were long lasting, with recipients earning salaries that were 41 percent higher four years later.

Because unconditional cash transfer programs are quite new, however, it is not yet clear whether their early promise can be replicated in other places or even why granting cash unconditionally seems to work better than either conditional cash transfers or microfinance. Experiments are under way to find out.

SUMMARY

L042.1 Describe how the World Bank distinguishes between industrially advanced countries and developing countries.

The majority of the world's nations are developing countries (low- and middle-income nations). While some DVCs have been realizing rapid growth rates in recent years, others have experienced little or no growth.

L042.2 List some of the obstacles to economic development.

Scarcities of natural resources make it more challenging—but certainly not impossible—for a nation to develop.

The large and rapidly growing populations in many DVCs contribute to low per capita incomes. Increases in per capita incomes frequently induce greater population growth, often reducing per capita incomes to near-subsistence levels. The demographic transition view, however, suggests that rising living standards must precede declining birthrates.

Most DVCs suffer from unemployment and underemployment. Labor productivity is low because of insufficient investment in physical and human capital.

In many DVCs, formidable obstacles impede both saving and investment. In some of the poorest DVCs, the savings potential is very low, and many savers transfer their funds to the IACs rather than invest them domestically. The lack of a vigorous entrepreneurial class and the weakness of investment incentives also impede capital accumulation.

Appropriate social and institutional changes and, in particular, the presence of the will to develop are essential ingredients in economic development.

L042.3 Explain the vicious circle of poverty that afflicts low-income nations.

The vicious circle of poverty brings together many of the obstacles to growth, supporting the view that poor countries stay poor because

of their poverty. Low incomes inhibit saving and the accumulation of physical and human capital, making it difficult to increase productivity and incomes. Overly rapid population growth, however, may offset promising attempts to break the vicious circle.

LO42.4 Discuss the role of government in promoting economic development within low-income nations.

The nature of the obstacles to growth—the absence of an entrepreneurial class, the dearth of infrastructure, the saving-investment dilemma, and the presence of social-institutional obstacles to growth—suggests that government should play a major role in initiating growth. Economists suggest that DVCs could make further development progress through such policies as establishing the rule of law, building infrastructure, opening their economies to international trade, setting realistic exchange rates, encouraging foreign direct investment, building human capital, encouraging entrepreneurship, controlling population growth, and making peace with neighbors. However, the corruption and maladministration that are

common to the public sectors of many DVCs suggest that government may not be very effective in instigating growth.

LO42.5 Describe how industrial nations attempt to aid low-income countries.

Advanced nations can encourage development in the DVCs by reducing IAC trade barriers and by directing foreign aid (official development assistance) to the neediest nations, providing debt forgiveness to the poorest DVCs, allowing temporary low-skilled immigration from the DVCs, and discouraging arms sales to the DVCs. Critics of foreign aid, however, say that it (a) creates DVC dependency, (b) contributes to the growth of bureaucracies and centralized economic control, and (c) is rendered ineffective by corruption and mismanagement.

In recent years the IACs have reduced foreign aid to the DVCs but have increased direct investment and other private capital flows to the DVCs. Little of the foreign direct investment, however, has gone to the poorest DVCs. Also, foreign direct investment plummeted during the worldwide recession of 2007–2009.

DISCUSSION QUESTIONS

1. What are the four categories used by the World Bank to classify nations on the basis of national income per capita? Identify any two nations of your choice for each of the four categories. **LO42.1**
2. Explain how the absolute per capita income gap between rich and poor nations might increase, even though per capita income (or output) is growing faster in DVCs than in IACs. **LO42.1**
3. Explain how each of the following can be obstacles to the growth of income per capita in the DVCs: lack of natural resources, large populations, low labor productivity, poor infrastructure, and capital flight. **LO42.2**
4. What is the demographic transition? Contrast the demographic transition view of population growth with the traditional view that slower population growth is a prerequisite for rising living standards in the DVCs. **LO42.2**
5. As it relates to the vicious circle of poverty, what is meant by the saying “Some DVCs stay poor because they are poor”? Change the box labels as necessary in Figure 42.3 to explain rapid economic growth in countries such as South Korea and Chile. What factors other than those contained in the figure might contribute to that growth? **LO42.3**
6. Because real capital is supposed to earn a higher return where it is scarce, how do you explain the fact that most international investment flows to the IACs (where capital is relatively abundant) rather than to the DVCs (where capital is very scarce)? **LO42.3**
7. List and discuss five policies that DVC governments might undertake to promote economic development and expansion of income per capita in their countries? **LO42.4**
8. Do you think that the nature of the problems the DVCs face requires a government-directed or a private-sector-directed development process? Explain your reasoning. **LO42.4**

9. Why do you think there is so much government corruption in some developing countries? **L042.4**
10. What types of products do the DVCs typically export? How do those exports relate to the law of comparative advantage? How do tariffs by IACs reduce the standard of living of DVCs? **L042.5**
11. Do you favor debt forgiveness to all DVCs, just the poorest ones, or none at all? What incentive problem might debt relief create? Would you be willing to pay \$20 a year more in personal income taxes for debt forgiveness? How about \$200? How about \$2,000? **L042.5**
12. Do you think that IACs such as the United States should open their doors wider to the immigration of low-skilled DVC workers as a way to help DVCs develop? Do you think that it is appropriate for students from DVC nations to stay in IAC nations to work and build careers? **L042.5**
13. **LAST WORD** Explain the differences among microcredit, conditional cash transfers, and unconditional cash transfers. Then explain how effective each policy has been.

REVIEW QUESTIONS

1. True or False: The term *developing country* (DVC) is applied to rich nations like the United States and Germany because their economies are always growing quickly by developing new technologies. **L042.1**
2. True or False: A DVC that has little in the way of natural resources is destined to remain poor. **L042.2**
3. Suppose a country's total output is growing 10 percent per year, but its population is growing 11 percent per year. What will happen to living standards? **L042.2**
 - a. Rise.
 - b. Fall.
 - c. Remain the same.
4. A DVC's population is growing 2 percent per year and output is growing 3 percent per year. If the government wants to improve living standards over coming decades, which of the following would probably be the best savings rate for the economy? **L042.2**
 - a. 0 percent.
 - b. 2 percent.
 - c. 5 percent.
 - d. 10 percent.
5. Compare a hypothetical DVC with a hypothetical IAC. In the DVC, average per capita income is \$500 per year. In the IAC, average per capita income is \$40,000 per year. If both countries have a savings rate of 10 percent per year, the amount of savings per capita in the DVC will be _____ per person per year, while in the IAC it will be _____ per person per year. **L042.3**
 - a. \$50; \$4,000.
 - b. \$5; \$400.
 - c. \$450; \$36,000.
 - d. None of the above.
6. Which of the following policies would economists consider to be actions that a DVC government might take that would *improve* growth prospects? **L042.4**
Choose one or more answers from the choices shown.
 - a. Helping to extend the banking system to the rural poor.
 - b. Passing high tariffs against foreign products.
 - c. Constructing better ports, roads, and Internet networks.
 - d. Charging high fees for public elementary schools.
7. True or False: Economists are unanimous that foreign aid greatly helps DVCs. **L042.5**
8. True or False: Some economists argue that the single best thing that IACs could do for DVCs in terms of economic growth would be to eliminate trade barriers between IACs and DVCs. **L042.5**

PROBLEMS

1. Assume a DVC and an IAC currently have real per capita outputs of \$500 and \$5,000, respectively. If both nations have a 3 percent increase in their real per capita outputs, by how much will the per capita output gap change? **L042.1**
2. Assume that a very tiny and very poor DVC has income per capita of \$300 and total national income of \$3 million. How large is its population? If its population grows by 2 percent in some year while its total income grows by 3 percent, what will be its new income per capita rounded to full dollars? If the population had not grown during the year, what would have been its income per capita? **L042.2**

GLOSSARY

Note: Terms set in *italic type* are defined separately in this glossary.

45° (degree) line The reference line in a two-dimensional graph that shows equality between the variable measured on the *horizontal axis* and the variable measured on the *vertical axis*. In the *aggregate expenditures model*, the line along which the value of output (measured horizontally) is equal to the value of *aggregate expenditures* (measured vertically).

ability-to-pay principle The idea that those who have greater *income* (or *wealth*) should pay a greater proportion of it as taxes than those who have less income (or wealth).

accounting profit The *total revenue* of a *firm* less its *explicit costs*; the profit (or net income) that appears on accounting statements and that is reported to the government for tax purposes.

acreage allotments A pre-1996 government program that limited the total number of acres to be used in producing (reduced amounts of) various food and fiber products and allocated these acres among individual farmers. These farmers had to limit their plantings to the allotted number of acres to obtain *price supports* for their crops.

actively managed funds *Mutual funds* that have portfolio managers who constantly buy and sell *assets* in an attempt to generate high returns.

actual reserves The funds that a bank has on deposit at the *Federal Reserve Bank* of its district (plus its *vault cash*).

adverse selection problem A problem arising when information known to one party to a contract or agreement is not known to the other party, causing the latter to incur major costs. Example: Individuals who have the poorest health are most likely to buy health insurance.

AFL-CIO An acronym for the American Federation of Labor–Congress of Industrial Organizations; the largest federation of *labor unions* in the United States.

agency shop A place of employment where the employer may hire either *labor union* members or nonmembers but where those employees who do not join the union must either pay union dues or donate an equivalent amount of money to a charity.

aggregate A collection of specific economic units treated as if they were one unit. Examples: the *prices* of all individual *goods* and *services* are combined into the *price level*, and all units of output are aggregated into *gross domestic product*.

aggregate demand A schedule or curve that shows the total quantity of *goods* and *services* that would be demanded (purchased) at various *price levels*.

aggregate demand–aggregate supply (AD-AS) model The macroeconomic model that uses *aggregate demand* and *aggregate supply* to determine and explain the *price level* and the *real domestic output* (*real gross domestic product*).

aggregate expenditures schedule A table of numbers showing the total amount spent on *final goods* and *final services* at different levels of *real gross domestic product* (*real GDP*).

aggregate supply A schedule or curve showing the total quantity of *goods* and *services* that would be supplied (produced) at various *price levels*.

aggregate supply shocks Sudden, large changes in resource costs that shift an economy's aggregate supply curve.

agribusiness The portion of the agricultural and food product industries that is dominated by large corporations.

Agricultural Act of 2014 The agricultural law enacted in the United States in 2014 that eliminated *direct payments* and *counter-cyclical payments* in favor of two types of *crop insurance*—*price loss coverage* and *agricultural risk coverage*.

agricultural risk coverage A form of *crop insurance* that pays out if the total revenue generated by all the farmers planting a given crop in a given county falls below a predetermined value.

Alcoa case A 1945 case in which the courts ruled that the possession of monopoly power, no matter how reasonably that power had been used, was a violation of the antitrust laws; temporarily overturned the *rule of reason* applied in the *U.S. Steel case*.

allocative efficiency The apportionment of resources among *firms* and industries to obtain the production of the products most wanted by society (consumers); the output of each product at which its *marginal cost* and *price* or *marginal benefit* are equal, and at which the sum of *consumer surplus* and *producer surplus* is maximized.

anchoring The tendency people have to unconsciously base, or “anchor,” the valuation of an item they are currently thinking about on recently considered but logically irrelevant information.

anticipated inflation Increases in the *price level* (*inflation*) that occur at the expected rate.

antitrust laws Legislation (including the *Sherman Act* and *Clayton Act*) that prohibits anticompetitive business activities such as *price fixing*, bid rigging, monopolization, and *tying contracts*.

antitrust policy The use of the *antitrust laws* to promote *competition* and *economic efficiency*.

arbitrage The activity of selling one *asset* and buying an identical or nearly identical asset to benefit from temporary differences in *prices* or *rates of return*; the practice that equalizes prices or returns on similar financial instruments and thus eliminates further opportunities for riskless financial gains.

asset demand for money The amount of *money* people want to hold as a *store of value*; this amount varies inversely with the *interest rate*.

asymmetric information A situation where one party to a market transaction has much more information about a product or service than the other. The result may be an under- or overallocation of resources.

average expected rate of return The *probability-weighted average* of an investment's possible future returns.

average fixed cost (AFC) A *firm's* total *fixed cost* divided by output (the quantity of product produced).

average product (AP) The total output produced per unit of a *resource* employed (*total product* divided by the quantity of that employed resource).

average propensity to consume (APC) Fraction (or percentage) of *disposable income* that *households* spend on *consumer goods*; consumption divided by *disposable income*.

average propensity to save (APS) Fraction (or percentage) of *disposable income* that *households* save; *saving* divided by *disposable income*.

average revenue Total revenue from the sale of a product divided by the quantity of the product sold (demanded); equal to the *price* at which the product is sold when all units of the product are sold at the same price.

average tax rate Total tax paid divided by total *taxable income* or some other base (such as total income) against which to compare the amount of tax paid. Expressed as a percentage.

average total cost (ATC) A firm's *total cost* divided by output (the quantity of product produced); equal to *average fixed cost* plus *average variable cost*.

average variable cost (AVC) A firm's total *variable cost* divided by output (the quantity of product produced).

backflows The return of workers to the countries from which they originally emigrated.

backward induction A method for solving for the *subgame perfect Nash equilibrium* of a *sequential game* that is presented in *extensive form*.

balance of payments A summary of all the financial transactions that take place between the individuals, *firms*, and governmental units of one nation and those of all other nations during a year.

balance on capital and financial account The sum of the *capital account balance* and the *financial account balance*.

balance on current account The exports of *goods* and *services* of a nation less its imports of goods and services plus its *net investment income* and *net transfers* in a year.

balance on goods and services The exports of *goods* and *services* of a nation less its imports of goods and services in a year.

balance sheet A statement of the *assets*, *liabilities*, and *net worth* of a *firm* or individual at some given time.

balance-of-payments deficit Misleading term used in the financial press to describe a net decline in a country's *foreign exchange reserves* as it buys and sells foreign exchange in order to maintain a *fixed exchange rate*. The term is misleading because a nation's *balance of payments* statement must always balance (be zero) and can never be in deficit (less than zero).

balance-of-payments surplus Misleading term used in the financial press to describe a net increase in a country's *foreign exchange reserves* as it buys and sells foreign exchange in order to maintain a *fixed exchange rate*. The term is misleading because a nation's *balance of payments* statement must always balance (be zero) and can never be in surplus (greater than zero).

bankrupt A legal situation in which an individual or *firm* finds that it cannot make timely interest payments on money it has

borrowed. In such cases, a bankruptcy judge can order the individual or firm to liquidate (turn into cash) its assets in order to pay lenders at least some portion of the amount they are owed.

barrier to entry Anything that artificially prevents the entry of *firms* into an *industry*.

barter The direct exchange of one *good* or *service* for another good or service.

base year The year with which other years are compared when an index is constructed; for example, the base year for a *price index*.

beaten paths Migration routes taken previously by family, relatives, friends, and other migrants.

behavioral economics The branch of economic theory that combines insights from economics, psychology, and biology to make more accurate predictions about human behavior than conventional *neoclassical economics*, which is hampered by its core assumptions that people are fundamentally *rational* and almost entirely self-interested. Behavioral economics can explain *framing effects*, *anchoring*, *mental accounting*, the *endowment effect*, *status quo bias*, *time inconsistency*, and *loss aversion*.

benefits-received principle The idea that those who receive the benefits of *goods* and *services* provided by government should pay the taxes required to finance them.

beta A relative measure of *nondiversifiable risk* that measures how the nondiversifiable risk of a given *asset* or *portfolio* compares with that of the *market portfolio* (the portfolio that contains every asset available in the financial markets).

bilateral monopoly A market in which there is a single seller (*monopoly*) and a single buyer (*monopsony*).

Board of Governors The seven-member group that supervises and controls the money and banking system of the United States; the Board of Governors of the *Federal Reserve System*; the Federal Reserve Board.

bond A financial device through which a borrower (a *firm* or government) is obligated to pay the principal and interest on a loan at specific dates in the future.

brain drains The exit or *emigration* of highly educated, highly skilled workers from a country.

break-even income The level of *disposable income* at which *households* plan to consume (spend) all their income and to save none of it.

break-even point An output at which a *firm* makes a *normal profit* (*total revenue* = *total cost*) but not an *economic profit*.

Bretton Woods system The international monetary system developed after the Second World War in which *adjustable pegs* were employed, the *International Monetary Fund* help stabilize foreign exchange rates, and gold and the dollar were used as *international monetary reserves*.

British thermal unit (BTU) The amount of energy required to raise the temperature of 1 pound of water by 1 degree Fahrenheit.

budget constraint The limit that the size of a consumer's income (and the *prices* that must be paid for *goods* and *services*) imposes on the ability of that consumer to obtain goods and services.

budget deficit The amount by which expenditures exceed revenues in any year.

budget line A line that shows the different combinations of two products a consumer can purchase with a specific money income, given the products' *prices*.

budget surplus The amount by which the revenues of the federal government exceed its expenditures in any year.

built-in stabilizer A mechanism that increases government's budget deficit (or reduces its surplus) during a recession and increases government's budget surplus (or reduces its deficit) during an expansion without any action by policymakers. The tax system is one such mechanism.

business cycle Recurring increases and decreases in the level of economic activity over periods of years; consists of peak, recession, trough, and expansion phases.

businesses Economic entities (*firms*) that purchase resources and provide *goods* and *services* to the economy.

capital Human-made resources (buildings, machinery, and equipment) used to produce *goods* and *services*; goods that do not directly satisfy human wants; also called capital goods. One of the four *economic resources*.

capital and financial account The section of a nation's *international balance of payments* that records (1) debt forgiveness by and to foreigners and (2) foreign purchases of assets in the United States and U.S. purchases of assets abroad.

capital flight The transfer of savings from *developing countries* to *industrially advanced countries* to avoid government expropriation, taxation, or higher rates of *inflation*, or simply to realize greater returns on *financial investments*.

capital gain The gain realized when *securities* or properties or other assets are sold for a *price* greater than the price paid for them.

capital goods (See *capital*.)

capital-intensive goods Products that require relatively large amounts of *capital* to produce.

capital-saving technology An improvement in *technology* that permits a greater quantity of a product to be produced with a specific amount of *capital* (or permits the same amount of the product to be produced with a smaller amount of capital).

capital-using technology An improvement in *technology* that requires the use of a greater amount of *capital* to produce a specific quantity of a product.

capricious-universe view The view held by some people that fate and outside events, rather than hard work and enterprise, will determine their economic destinies.

cartel A formal agreement among *firms* (or countries) in an *industry* to set the *price* of a product and establish the outputs of the individual firms (or countries) or to divide the market for the product geographically.

cease-and-desist order An order from a court or government agency to a corporation or individual to stop engaging in a specified practice.

Celler-Kefauver Act The federal law of 1950 that amended the *Clayton Act* by prohibiting the acquisition of the assets of one *firm* by another firm when the effect would be less competition.

change in demand A movement of an entire *demand curve* or schedule such that the *quantity demanded* changes at every particular *price*; caused by a change in one or more of the *determinants of demand*.

change in quantity demanded A change in the *quantity demanded* along a fixed *demand curve* (or within a fixed demand schedule) as a result of a change in the *price* of the product.

change in quantity supplied A change in the *quantity supplied* along a fixed *supply curve* (or within a fixed supply schedule) as a result of a change in the product's *price*.

change in supply A movement of an entire *supply curve* or schedule such that the *quantity supplied* changes at every particular *price*; caused by a change in one or more of the *determinants of supply*.

Change to Win A loose federation of American unions that includes the Service Workers and Teamsters unions; the second largest union federation after the *AFL-CIO*.

checkable deposit Any deposit in a *commercial bank* or *thrift institution* against which a check may be written.

circular flow diagram An illustration showing the flow of *resources* from *households* to *firms* and of products from firms to households. These flows are accompanied by reverse flows of money from firms to households and from households to firms.

Clayton Act The federal antitrust law of 1914 that strengthened the *Sherman Act* by making it illegal for *firms* to engage in certain specified practices including *tying contracts*, *interlocking directorates*, and certain forms of *price discrimination*.

closed shop A place of employment where only workers who are already members of a labor union may be hired.

Coase theorem The idea, first stated by economist Ronald Coase, that some *externalities* can be resolved through private negotiations among the affected parties.

cognitive biases Misperceptions or misunderstandings that cause *systematic errors*. Most result either (1) from *heuristics* that are prone to *systematic errors* or (2) because the brain is attempting to solve a type of problem (such as a calculus problem) for which it was not evolutionarily evolved and for which it has little innate capability.

collateral The pledge of specific assets by a borrower to a lender with the understanding that the lender will get to keep the assets if the borrower fails to repay the loan with cash.

collective bargaining The negotiation of labor contracts between *labor unions* and *firms* or government entities.

collective-action problem The idea that getting a group to pursue a common, collective goal gets harder the larger the group's size. Larger groups are more costly to organize and their members more difficult to motivate because the larger the group, the smaller each member's share of the benefits if the group succeeds.

collusion A situation in which *firms* act together and in agreement (collude) to fix *prices*, divide a market, or otherwise restrict competition.

command system A method of organizing an economy in which property resources are publicly owned and government uses *central economic planning* to direct and coordinate economic activities; *socialism*; communism. Compare with *market system*.

commercial bank A *firm* that engages in the business of banking (accepts deposits, offers checking accounts, and makes loans).

comparative advantage A situation in which a person or country can produce a specific product at a lower opportunity cost than some other person or country; the basis for specialization and trade.

compensating differences Differences in the *wages* received by workers in different jobs to compensate for the nonmonetary differences between the jobs.

compensating wage differential (See *compensating differences*.)

competition The effort and striving between two or more independent rivals to secure the business of one or more third parties by offering the best possible terms.

complementary goods Products and *services* that are used together. When the *price* of one falls, the demand for the other increases (and conversely).

complementary resources Productive inputs that are used jointly with other inputs in the production process; resources for which a decrease in the *price* of one leads to an increase in the demand for the other.

compound interest The accumulation of money that builds over time in an investment or interest-bearing account as new interest is earned on previous interest that is not withdrawn.

conditional cash transfers Anti-poverty programs in which households receive regular cash transfers (grants) as long as they keep their children in school and participate in preventative health-care programs.

conflict diamonds Diamonds that are mined and sold by combatants in war zones in Africa as a way to provide the currency needed to finance their military activities.

conglomerate merger The merger of two *firms* operating in separate industries or separate geographic areas so that neither firm is a supplier, customer, or competitor of the other; any merger that is neither a *horizontal merger* nor a *vertical merger*.

constant returns to scale The situation when a firm's *average total cost* of producing a product remains unchanged in the *long run* as the firm varies the size of its *plant* (and, hence, its output).

constant-cost industry An *industry* in which the entry and exit of *firms* have no effect on the *prices* firms in the industry must pay for resources and thus no effect on production costs.

consumer equilibrium In marginal utility theory, the combination of goods purchased that maximizes *total utility* by applying the *utility-maximizing rule*. In indifference curve analysis, the combination of goods purchased that maximizes *total utility* by enabling the consumer to reach the highest *indifference curve*, given the consumer's *budget line* (or *budget constraint*).

consumer goods Products and *services* that satisfy human wants directly.

Consumer Price Index (CPI) An index that measures the *prices* of a fixed "market basket" of some 300 *goods* and *services* bought by a "typical" consumer.

consumer sovereignty The determination by consumers of the types and quantities of *goods* and *services* that will be produced with the scarce resources of the economy; consumers' direction of production through their *dollar votes*.

consumer surplus The difference between the maximum *price* a consumer is (or consumers are) willing to pay for an additional unit of a product and its market price; the triangular area below the demand curve and above the market price.

consumption of fixed capital An estimate of the amount of *capital* worn out or used up (consumed) in producing the *gross domestic product*; also called depreciation.

consumption schedule A table of numbers showing the amounts *households* plan to spend for *consumer goods* at different levels of *disposable income*.

contractionary fiscal policy A decrease in *government purchases* of *goods* and *services*, an increase in *net taxes*, or some combination of the two, for the purpose of decreasing *aggregate demand* and thus controlling *inflation*.

coordination failure A situation in which people do not reach a mutually beneficial outcome because they lack some way to jointly coordinate their actions; a possible cause of macroeconomic instability.

copayment The percentage of (say, health care) costs that an insured individual pays while the insurer pays the remainder.

core inflation The underlying increases in the *price level* after volatile food and energy *prices* are removed.

corporate income tax A tax levied on the net income (accounting profit) of corporations.

corporation A legal entity ("person") chartered by a state or the federal government that is distinct and separate from the individuals who own it.

corruption The misuse of government power, with which one has been entrusted or assigned, to obtain private gain; includes payments from individuals or companies to secure advantages in obtaining government contracts, avoiding government regulations, or obtaining inside knowledge about forthcoming policy changes.

cost-benefit analysis A comparison of the *marginal costs* of a project or program with the *marginal benefits* to decide whether or not to employ resources in that project or program and to what extent.

cost-of-living adjustment (COLA) An automatic increase in the incomes (*wages*) of workers when *inflation* occurs; often included in *collective bargaining* agreements between *firms* and *unions*. Cost-of-living adjustments are also guaranteed by law for *Social Security* benefits and certain other government *transfer payments*.

cost-push inflation Increases in the *price level* (*inflation*) resulting from an increase in resource costs (for example, raw-material prices) and hence in *per-unit production costs*; inflation caused by reductions in *aggregate supply*.

Council of Economic Advisers (CEA) A group of three persons that advises and assists the president of the United States on economic matters (including the preparation of the annual *Economic Report of the President*).

countercyclical payments (CCPs) Cash *subsidies* paid to farmers when market *prices* for certain crops drop below targeted prices. Payments are based on previous production and are received regardless of the current crop grown.

creative destruction The hypothesis that the creation of new products and production methods destroys the market power of existing monopolies.

credible threat In a *sequential game* with two players, a statement made by Player 1 that truthfully (credibly) threatens a penalizing action against Player 2 if Player 2 does something that Player 1 does not want Player 2 to do. Opposite of *empty threat*.

crop insurance Insurance that farmers can purchase that will pay out if crop selling prices or crop revenues fall below predetermined values.

cross elasticity of demand The ratio of the percentage change in *quantity demanded* of one good to the percentage change in the *price* of some other good. A positive coefficient indicates the two products are *substitute goods*; a negative coefficient indicates they are *complementary goods*.

crowding-out effect A rise in interest rates and a resulting decrease in *planned investment* caused by the federal government's increased borrowing to finance budget deficits and refinance debt.

currency intervention A government's buying and selling of its own currency or foreign currencies to alter international exchange rates.

current account The section in a nation's *international balance of payments* that records its exports and imports of *goods and services*, its *net investment income*, and its *net transfers*.

cyclical asymmetry The idea that *monetary policy* may be more successful in slowing expansions and controlling *inflation* than in extracting the economy from severe recession.

cyclical deficit Federal *budget deficit* that is caused by a recession and the consequent decline in tax revenues.

cyclical unemployment A type of *unemployment* caused by insufficient total spending (insufficient *aggregate demand*) and which typically begins in the *recession* phase of the *business cycle*.

cyclically adjusted budget The estimated annual budget deficit or surplus that would occur under existing tax rates and government spending levels if the economy were to operate at its *full-employment* level of GDP for a year; the *full-employment* budget deficit or surplus.

deadweight loss (See *efficiency loss*.)

debt crisis An economic crisis in which government debt has risen so high that the government is unable to borrow any more money due to people losing faith in the government's ability to repay. Leads to either massive spending cuts or large tax increases, either of which will likely plunge the economy into a *recession*.

decision node In a *strategic game* that is presented in *extensive form*, a point (node) at which a player must make a decision. The decision leads to either another *decision node* or a *terminal node*.

decreasing-cost industry An *industry* in which expansion through the entry of *firms* lowers the *prices* that firms in the industry must pay for resources and therefore decreases their production costs.

deductible The dollar sum of (for example, health care) costs that an insured individual must pay before the insurer begins to pay.

defaults Situations in which borrowers stop making loan payments or do not pay back loans that they took out and are now due.

defensive medicine The recommendation by physicians of more tests and procedures than are warranted medically or economically as a way of protecting themselves against later malpractice suits.

deflation A decline in the general level of *prices* in an economy; a decline in an economy's *price level*.

demand A schedule or curve that shows the various amounts of a product that consumers are willing and able to purchase at each of a series of possible *prices* during a specified period of time.

demand curve A curve that illustrates the *demand* for a product by showing how each possible *price* (on the *vertical axis*) is associated with a specific *quantity demanded* (on the *horizontal axis*).

demand factor (in growth) The requirement that *aggregate demand* increase as fast as *potential output* if *economic growth* is to proceed as quickly as possible.

demand schedule A table of numbers showing the amounts of a *good* or *service* buyers are willing and able to purchase at various *prices* over a specified period of time.

demand shocks Sudden, unexpected changes in demand.

demand-pull inflation Increases in the *price level (inflation)* resulting from increases in *aggregate demand*.

demand-side market failures Underallocations of resources that occur when private demand curves understate consumers' full willingness to pay for a *good* or *service*.

demographers Scientists who study the characteristics of human populations.

demographic transition The massive decline in birth rates that occurs once a developing country achieves higher standards of living because the perceived marginal cost of additional children begins to exceed the perceived marginal benefit.

dependent variable A variable that changes as a consequence of a change in some other (independent) variable; the "effect" or outcome.

deregulation The removal of most or even all of the government regulation and laws designed to supervise an industry. Sometimes undertaken to combat *regulatory capture*.

derived demand The demand for a resource that depends on the demand for the products it helps to produce.

determinants of aggregate demand Factors such as consumption spending, *investment*, government spending, and *net exports* that, if they change, shift the aggregate demand curve.

determinants of aggregate supply Factors such as input prices, *productivity*, and the legal-institutional environment that, if they change, shift the aggregate supply curve.

determinants of demand Factors other than *price* that determine the quantities demanded of a *good* or *service*. Also referred to as "demand shifters" because changes in the determinants of demand will cause the *demand curve* to shift either right or left.

determinants of supply Factors other than *price* that determine the quantities supplied of a *good* or *service*. Also referred to as "supply shifters" because changes in the determinants of supply will cause the *supply curve* to shift either right or left.

devaluation A decrease in the governmentally defined value of a currency.

developing countries (DVCs) Many countries of Africa, Asia, and Latin America that are characterized by lack of capital goods, use of nonadvanced technologies, low literacy rates, high unemployment, relatively rapid population growth, and labor forces heavily committed to agriculture.

diagnosis-related group (DRG) system Payments to doctors and hospitals under *Medicare* based on which of hundreds of carefully detailed diagnostic categories best characterize each patient's condition and needs.

dictator game A mutually anonymous behavioral economics game in which one person ("the dictator") unilaterally determines how to split an amount of money with the second player.

differentiated oligopoly An *oligopoly* in which *firms* produce a *differentiated product*.

diffusion The spread of an *innovation* through its widespread imitation.

diminishing marginal utility (See *law of diminishing marginal utility*.)

direct payments Cash subsidies paid to farmers based on past production levels; a permanent transfer payment unaffected by current crop *prices* and current production.

direct relationship The relationship between two variables that change in the same direction, for example, product *price* and quantity supplied; a positive relationship.

discount rate The interest rate that the *Federal Reserve Banks* charge on the loans they make to *commercial banks* and *thrift institutions*.

discouraged workers Employees who have left the *labor force* because they have not been able to find employment.

discrimination The practice of according individuals or groups inferior treatment in hiring, occupational access, education and training, promotion, wage rates, or working conditions even though they have the same abilities, education, skills, and work experience as other workers.

discrimination coefficient A measure of the cost or disutility of prejudice; the monetary amount an employer is willing to pay to hire a preferred worker rather than a nonpreferred worker of the same ability.

diseconomies of scale The situation when a firm's *average total cost* of producing a product increases in the *long run* as the firm increases the size of its *plant* (and, hence, its output).

disinflation A reduction in the rate of *inflation*.

disposable income (DI) *Personal income* less personal taxes; income available for *personal consumption expenditures* and *personal saving*.

diversifiable risk Investment *risk* that investors can reduce via *diversification*; also called idiosyncratic risk.

diversification The strategy of investing in a large number of investments in order to reduce the overall risk to an entire investment *portfolio*.

dividends Payments by a corporation of all or part of its profit to its stockholders (the corporate owners).

division of labor The separation of the work required to produce a product into a number of different tasks that are performed by different workers; *specialization* of workers.

Doha Development Agenda The latest, uncompleted (as of late 2013) sequence of trade negotiations by members of the *World Trade Organization*; named after Doha, Qatar, where the set of negotiations began. Also called the Doha Round.

dollar votes The "votes" that consumers cast for the production of preferred products when they purchase those products rather than the alternatives that were also available.

domestic price The *price* of a *good* or *service* within a country, determined by domestic demand and supply.

dominant strategy In a strategic interaction (*game*) between two or more players, a course of action (strategy) that a player will wish to undertake no matter what the other players choose to do.

dumping The sale of a product in a foreign country at *prices* either below cost or below the prices commonly charged at home.

DuPont cellophane case The antitrust case brought against DuPont in which the U.S. Supreme Court ruled (in 1956) that while DuPont had a monopoly in the narrowly defined market for cellophane, it did not monopolize the more broadly defined market for flexible packaging materials. It was thus not guilty of violating the *Sherman Act*.

durable good A consumer good with an expected life (use) of three or more years.

earmarks Narrow, specially designated spending authorizations placed in broad legislation by senators and representatives for the purpose of providing benefits to *firms* and organizations within their constituencies. Earmarked projects are exempt from competitive bidding and normal evaluation procedures.

earned-income tax credit (EITC) A refundable federal *tax credit* for low-income working people designed to reduce poverty and encourage labor-force participation.

economic cost A payment that must be made to obtain and retain the *services* of a *resource*; the income a *firm* must provide to a resource supplier to attract the resource away from an alternative use; equal to the quantity of other products that cannot be produced when resources are instead used to make a particular product.

economic growth (1) An outward shift in the *production possibilities curve* that results from an increase in resource supplies or quality or an improvement in *technology*; (2) an increase of real output (*gross domestic product*) or real output per capita.

economic immigrants International migrants who have moved from one country to another to obtain economic gains such as better employment opportunities.

economic investment (See *investment*.)

economic perspective A viewpoint that envisions individuals and institutions making rational decisions by comparing the marginal benefits and marginal costs associated with their actions.

economic principle A widely accepted generalization about the economic behavior of individuals or institutions.

economic profit The return flowing to those who provide the economy with the *economic resource* of *entrepreneurial ability*; the *total revenue* of a *firm* less its *economic costs* (which include both *explicit costs* and *implicit costs*); also called "pure profit" and "above-normal profit."

economic rent The *price* paid for the use of land and other natural resources that are in fixed (*perfectly inelastic*) supply.

economic resources The *land*, *labor*, *capital*, and *entrepreneurial ability* that are used to produce *goods* and *services*; the *factors of production*.

economic system A particular set of institutional arrangements and a coordinating mechanism for solving the *economizing problem*; a method of organizing an economy, of which the *market system* and the *command system* are the two general types.

economics The social science concerned with how individuals, institutions, and society make optimal (best) choices under conditions of scarcity.

economies of scale The situation when a firm's *average total cost* of producing a product decreases in the *long run* as the firm increases the size of its *plant* (and, hence, its output).

economizing problem The choices necessitated because society's economic wants for *goods* and *services* are unlimited but the resources available to satisfy these wants are limited (scarce).

efficiency factor (in growth) The capacity of an economy to achieve *allocative efficiency* and *productive efficiency* and thereby fulfill the potential for growth that the *supply factors (of growth)* make possible; the capacity of an economy to achieve *economic efficiency* and thereby reach the optimal point on its *production possibilities curve*.

efficiency gains from migration The increases in total worldwide output that take place if the additions to output from *immigration* in the destination nation exceed the loss of output from *emigration* from the origin nation.

efficiency loss Reductions in combined consumer and producer surplus caused by an underallocation or overallocation of resources to the production of a *good* or *service*. Also called *deadweight loss*.

efficiency loss of a tax The loss of *net benefits* to society because a tax reduces the production and consumption of a taxed good below the level of *allocative efficiency*. Also called the *deadweight loss* of the tax.

efficiency wage An above-market (above-equilibrium) *wage* that minimizes wage costs per unit of output by encouraging greater effort or reducing turnover.

elastic demand Product or resource demand whose *price elasticity of demand* is greater than 1, so that any given percentage change in *price* leads to a larger percentage change in *quantity demanded*. As a result, quantity demanded is relatively sensitive to (elastic with respect to) price.

elasticity of resource demand A measure of the responsiveness of *firms* to a change in the *price* of a particular *resource* they employ or use; the percentage change in the quantity demanded of the *resource* divided by the percentage change in its *price*.

employer mandate The requirement under the *Patient Protection and Affordable Care Act (PPACA)* of 2010 that firms with 50 or more employees pay for insurance policies for their employees or face a fine of \$2,000 per employee per year. Firms with fewer than 50 employees are exempt.

empty threat In a *sequential game* with two players, a non-credible (bluffing) statement made by Player 1 that threatens a penalizing action against Player 2 if Player 2 does something that Player 1 does not want Player 2 to do. Opposite of *credible threat*.

endowment effect The tendency people have to place higher valuations on items they possess (are endowed with) than on identical items that they do not possess; perhaps caused by *loss aversion*.

entitlement programs Government programs such as *social insurance*, *Medicare*, and *Medicaid* that guarantee (entitle) particular levels of transfer payments or noncash benefits to all who fit the programs' criteria.

entrepreneurial ability The human resource that combines the other *economic resources* of *land*, *labor*, and *capital* to produce new products or make innovations in the production of existing products; provided by *entrepreneurs*.

entrepreneurs Individuals who provide *entrepreneurial ability* to *firms* by setting strategy, advancing innovations, and bearing the financial risk if their firms do poorly.

equality-efficiency trade-off The decrease in *economic efficiency* that may accompany a decrease in *income inequality*; the presumption that some income inequality is required to achieve economic efficiency.

equation of exchange $MV = PQ$, in which *M* is the supply of *money*, *V* is the *velocity* of money, *P* is the *price level*, and *Q* is the physical volume of *final goods* and *final services* produced.

equilibrium GDP (See *equilibrium real domestic output*.)

equilibrium position In the indifference curve model, the combination of two goods at which a consumer maximizes his or her *utility* (reaches the highest attainable *indifference curve*), given a limited amount to spend (a *budget constraint*).

equilibrium price The *price* in a competitive market at which the *quantity demanded* and the *quantity supplied* are equal, there is neither a shortage nor a surplus, and there is no tendency for price to rise or fall.

equilibrium price level In the *aggregate demand–aggregate supply (AD-AS) model*, the *price level* at which *aggregate demand* equals *aggregate supply*; the price level at which the aggregate demand curve intersects the aggregate supply curve.

equilibrium quantity (1) The quantity at which the intentions of buyers and sellers in a particular market match at a particular *price* such that the *quantity demanded* and the *quantity supplied* are equal; (2) the profit-maximizing output of a *firm*.

equilibrium real output (See *equilibrium real domestic output*.)

equilibrium world price The *price* of an internationally traded product that equates the quantity of the product demanded by importers with the quantity of the product supplied by exporters; the price determined at the intersection of the export supply curve and the import demand curve.

European Union (EU) An association of 28 European nations (as of mid-2013) that has eliminated tariffs and quotas among them, established common tariffs for imported goods from outside the member nations, eliminated barriers to the free movement of capital, and created other common economic policies.

eurozone The 17 nations (as of 2013) of the 28-member (as of 2013) *European Union* that use the *euro* as their common *currency*. The eurozone countries are Austria, Belgium, Cyprus, Estonia, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, Malta, the Netherlands, Portugal, Slovakia, Slovenia, and Spain.

excess capacity *Plant* resources that are underused when imperfectly competitive *firms* produce less output than that associated with achieving minimum *average total cost*.

excess reserves The amount by which a *commercial bank's* or *thrift institution's actual reserves* exceed its *required reserves*; actual reserves minus required reserves.

exchange controls Restrictions that a government may impose over the quantity of foreign currency demand by its citizens and *firms* and over the *rate of exchange* as a way to limit the nation's quantity of *outpayments* relative to its quantity of *inpayments* (in order to eliminate a *payments deficit*).

excise tax A tax levied on the production of a specific product or on the quantity of the product purchased.

excludability The characteristic of a *private good*, for which the seller can keep nonbuyers from obtaining the good.

exclusive unionism The policy, pursued by many *craft unions*, in which a *union* first gets employers to agree to hire only union workers and then excludes many workers from joining the union so as to restrict the supply of labor and drive up wages. Compare with *inclusive unionism*. The policies typically employed by a *craft union*.

exit mechanism The method of resolving workplace dissatisfaction by quitting one's job and searching for another.

expansion The phase of the *business cycle* in which *real GDP*, *income*, and employment rise.

expansionary fiscal policy An increase in *government purchases* of *goods* and *services*, a decrease in *net taxes*, or some combination of the two for the purpose of increasing *aggregate demand* and expanding real output.

expansionary monetary policy *Federal Reserve System* actions to increase the *money supply*, lower *interest rates*, and expand *real GDP*; an easy money policy.

expectations The anticipations of consumers, *firms*, and others about future economic conditions.

expected rate of return The increase in profit a *firm* anticipates it will obtain by purchasing capital or engaging in research and development (*R&D*); expressed as a percentage of the total cost of the investment (or *R&D*) activity.

expected-rate-of-return curve As it relates to research and development (*R&D*), a curve showing the anticipated gain in *profit*, as a percentage of *R&D* expenditure, from an additional dollar spent on *R&D*.

expenditures approach The method that adds all expenditures made for *final goods* and *final services* to measure the *gross domestic product*.

explicit cost The monetary payment made by a *firm* to an outsider to obtain a *resource*.

export subsidy A government payment to a domestic producer to enable the *firm* to reduce the *price* of a *good* or *service* to foreign buyers.

export supply curve An upward-sloping curve that shows the amount of a product that domestic *firms* will export at each *world price* that is above the *domestic price*.

extensive form A visual representation of a *sequential game* that maps out every possible decision as well as the sequence in which decisions must be made. Also called game-tree format.

external public debt The portion of the public debt owed to foreign citizens, *firms*, and institutions.

externality A cost or benefit from production or consumption that accrues to someone other than the immediate buyers and sellers

of the product being produced or consumed (see *negative externality* and *positive externality*).

extraction cost All costs associated with extracting a natural resource and readying it for sale.

factors of production The four *economic resources*: *land*, *labor*, *capital*, and *entrepreneurial ability*.

fair-return price For *natural monopolies* subject to rate (*price*) regulation, the price that would allow the regulated monopoly to earn a *normal profit*; a price equal to *average total cost*.

fairness A person's opinion as to whether a price, wage, or allocation is considered morally or ethically acceptable.

farm commodities Agricultural products such as grains, milk, cattle, fruits, and vegetables that are usually sold to processors, who use the products as inputs in creating *food products*.

fast-second strategy An approach by a dominant *firm* in which it allows other firms in its *industry* to bear the risk of innovation and then quickly becomes the second firm to offer any successful new product or adopt any improved production process.

federal funds rate The interest rate that U.S. banks and other depository institutions charge one another on overnight loans made out of their *excess reserves*.

Federal Open Market Committee (FOMC) The 12-member group within the *Federal Reserve System* that decides U.S. *monetary policy* and how it is executed through *open-market operations* (in which the Fed buys and sells U.S. government securities to adjust the *money supply*).

Federal Reserve Banks The 12 banks chartered by the U.S. government that collectively act as the *central bank* of the United States. They set monetary policy and regulate the private banking system under the direction of the *Board of Governors* and the *Federal Open Market Committee*. Each of the 12 is a *quasi-public bank* and acts as a *banker's bank* in its designated geographic region.

Federal Reserve Note Paper money issued by the *Federal Reserve Banks*.

Federal Reserve System The U.S. central bank, consisting of the *Board of Governors* of the Federal Reserve and the 12 *Federal Reserve Banks*, which controls the lending activity of the nation's banks and thrifts and thus the *money supply*; commonly referred to as the "Fed."

Federal Trade Commission Act The federal law of 1914 that established the *Federal Trade Commission*.

fee for service In the health care *industry*, payment to physicians for each visit made or procedure performed.

final goods Goods that have been purchased for final use (rather than for resale or further processing or manufacturing.)

financial investment The purchase of a financial asset (such as a *stock*, *bond*, or *mutual fund*) or real asset (such as a house, land, or factories) or the building of such assets in the expectation of financial gain.

financial services industry The broad category of *firms* that provide financial products and services to help *households* and businesses earn *interest*, receive *dividends*, obtain *capital gains*, insure against losses, and plan for retirement. Includes *commercial banks*, *thrift institutions*, insurance companies, mutual fund companies, pension funds, investment banks, and *securities* firms.

first-mover advantage In *game theory*, the benefit obtained by the party that moves first in a *sequential game*. A situation that occurs in a *sequential game* if the player who gets to move first has an advantage in terms of final outcomes over the player(s) who move subsequently.

fiscal policy Changes in government spending and tax collections designed to achieve full employment, price stability, and economic growth; also called *discretionary fiscal policy*.

fishery A stock of fish or other marine animal that is composed of a distinct group, for example New England cod, Pacific tuna, or Alaskan crab.

fishery collapse A rapid decline in a *fishery's* population because its fish are being harvested faster than they can reproduce.

fixed cost Any cost that in total does not change when the *firm* changes its output.

fixed exchange rate A *rate of exchange* that is set in some way and therefore prevented from rising or falling with changes in currency supply and demand.

flexible exchange rate A *rate of exchange* that is determined by the international demand for and supply of a nation's money and that is consequently free to rise or fall because it is not subject to *currency interventions*. Also referred to as a "floating exchange rate."

flexible prices Product *prices* that freely move upward or downward when product demand or supply changes.

follower countries As it relates to *economic growth*, countries that adopt advanced technologies that previously were developed and used by *leader countries*.

food products Processed *farm commodities* sold through grocery stores and restaurants. Examples: bread, meat, fish, chicken, pork, lettuce, peanut butter, and breakfast cereal.

foreign direct investment *Financial investments* made to obtain a lasting ownership interest in *firms* operating outside the economy of the investor; may involve purchasing existing assets or building new production facilities.

foreign purchases effect The inverse relationship between the *net exports* of an economy and its *price level* relative to foreign price levels.

foreign exchange reserves Stockpiles of foreign currencies maintained by a nation's *central bank*. Obtained when the *central bank* sells local currency in exchange for foreign currency in the *foreign exchange market*.

four-firm concentration ratio The percentage of total *industry* sales accounted for by the top four *firms* in an industry.

fractional reserve banking system A system in which *commercial banks* and *thrift institutions* hold less than 100 percent of their checkable-deposit liabilities as reserves of *currency* held in bank vaults or as deposits at the *central bank*.

framing effects In *prospect theory*, changes in people's decision making caused by new information that alters the context, or "frame of reference," that they use to judge whether options are viewed as gains or losses relative to the *status quo*.

free-rider problem The inability of potential providers of an economically desirable *good* or *service* to obtain payment from those who benefit, because of *nonexcludability*.

freedom of choice The freedom of owners of property resources to employ or dispose of them as they see fit, of workers to enter any

line of work for which they are qualified, and of consumers to spend their incomes in a manner that they think is appropriate.

freedom of enterprise The freedom of *firms* to obtain economic resources, to use those resources to produce products of the firm's own choosing, and to sell their products in markets of their choice.

Freedom to Farm Act A law passed in 1996 that revamped 60 years of U.S. farm policy by ending *price supports* and *acreage allotments* for wheat, corn, barley, oats, sorghum, rye, cotton, and rice.

frictional unemployment A type of unemployment caused by workers voluntarily changing jobs and by temporary layoffs; unemployed workers between jobs.

full-employment rate of unemployment The *unemployment rate* at which there is no *cyclical unemployment* of the *labor force*; equal to between 5 and 6 percent in the United States because some *frictional* and *structural unemployment* are unavoidable.

future value The amount to which some current amount of *money* will grow if *interest* earned on the amount is left to compound over time. (*See compound interest.*)

gains from trade The extra output that trading partners obtain through specialization of production and exchange of *goods* and *services*.

game An interaction between two or more participants (players) that is strategic so that the choices (strategies) of every participant affect the incentives facing—and thus the choices made by—all of the other participants.

game theory The study of how people behave in strategic situations in which individuals must take into account not only their own possible actions but also the possible reactions of others. Originally developed to analyze the best ways to play games like poker and chess.

GDP gap Actual *gross domestic product* minus *potential output*; may be either a positive amount (a *positive GDP gap*) or a negative amount (a *negative GDP gap*).

General Agreement on Tariffs and Trade (GATT) The international agreement reached in 1947 in which 23 nations agreed to eliminate *import quotas*, negotiate reductions in *tariff* rates, and give each other equal and nondiscriminatory treatment. It now includes most nations and has become the *World Trade Organization*.

Gini ratio A numerical measure of the overall dispersion of income among *households*, families, or individuals; found graphically by dividing the area between the diagonal line and the *Lorenz curve* by the entire area below the diagonal line.

gold standard A historical system of fixed exchange rates in which nations defined their currencies in terms of gold, maintained fixed relationships between their stocks of gold and their money supplies, and allowed gold to be freely exported and imported.

government failure Inefficiencies in resource allocation caused by problems in the operation of the *public sector* (government). Specific examples include the *principal-agent problem*, the *special-interest effect*, the *collective-action problem*, *rent seeking*, and *political corruption*.

government purchases (G) Expenditures by government for *goods* and *services* that government consumes in providing public services as well as expenditures for publicly owned capital that has a

long lifetime; the expenditures of all governments in the economy for those *final goods* and *final services*.

gross domestic product (GDP) The total market value of all *final goods* and *final services* produced annually within the boundaries of a nation.

gross output (GO) The dollar value of the economic activity taking place at every stage of production and distribution. By contrast, *gross domestic product* (GDP) only accounts for the value of final output.

gross private domestic investment (Ig) Expenditures for newly produced *capital goods* (such as machinery, equipment, tools, and buildings) and for additions to inventories.

growth accounting The bookkeeping of the supply-side elements such as productivity and labor inputs that contribute to changes in *real GDP* over some specific time period.

H1-B provision A provision of the U.S. immigration law that allows the annual entry of 65,000 high-skilled workers in “specialty occupations” such as science, *R&D*, and computer programming to work legally and continuously in the United States for six years.

health maintenance organizations (HMOs) Health care providers that contract with employers, insurance companies, labor unions, or government units to provide health care for their workers or others who are insured.

health savings accounts (HSAs) Tax-free savings accounts into which people with high-deductible health insurance plans can place funds each year. Accumulated funds can be used to pay out-of-pocket medical expenses such as *deductibles* and *copayments*. Unused funds accumulate from year to year and can be used after retirement to supplement *Medicare*.

Herfindahl index A measure of the concentration and competitiveness of an *industry*; calculated as the sum of the squared percentage market shares of the individual *firms* in the industry.

heuristics The brain’s low-energy mental shortcuts for making decisions. They are “fast and frugal” and work well in most situations but in other situations result in *systematic errors*.

homogeneous oligopoly An *oligopoly* in which *firms* produce a *standardized product*.

horizontal axis The “left-right” or “west-east” measurement line on a graph or grid.

horizontal merger The merger into a single *firm* of two firms producing the same product and selling it in the same geographic market.

households Economic entities (of one or more persons occupying a housing unit) that provide *resources* to the economy and use the *income* received to purchase *goods* and *services* that satisfy economic wants.

human capital The knowledge and skills that make a person productive.

hyperinflation A very rapid rise in the *price level*; an extremely high rate of *inflation*.

illegal immigrants People who have entered a country unlawfully to reside there; also called unauthorized immigrants.

imitation problem The potential for a *firm*’s rivals to produce a close variation of (imitate) a *firm*’s new product or

process, greatly reducing the originator’s profit from *R&D* and *innovation*.

immediate market period The length of time during which the producers of a product are unable to change the quantity supplied in response to a change in price and in which there is a *perfectly inelastic supply*.

immediate short-run aggregate supply curve An *aggregate supply* curve for which *real output*, but not the *price level*, changes when the *aggregate demand* curve shifts; a horizontal *aggregate supply* curve that implies an inflexible price level.

imperfect competition All *market structures* except *pure competition*; includes *monopoly*, *monopolistic competition*, and *oligopoly*.

implicit cost The monetary income a *firm* sacrifices when it uses a *resource* it owns rather than supplying the resource in the market; equal to what the resource could have earned in the best-paying alternative employment; includes a *normal profit*.

import competition The competition that domestic *firms* encounter from the products and *services* of foreign producers.

import demand curve A downsloping curve showing the amount of a product that an economy will import at each *world price* below the *domestic price*.

import quota A limit imposed by a nation on the quantity (or total value) of a good that may be imported during some period of time.

incentive function The inducement that an increase in the price of a commodity gives to sellers to make more of it available (and conversely for a decrease in *price*), and the inducement that an increase in price offers to buyers to purchase smaller quantities (and conversely for a decrease in price).

incentive pay plan A compensation structure that ties worker pay directly to performance. Such plans include piece rates, bonuses, *stock options*, commissions, and *profit-sharing plans*.

inclusive unionism The policy, pursued by *industrial unions*, in which a *union* attempts to include every worker in a given *industry* so as to be able to restrict the entire industry’s labor supply and thereby raise wages. Compare with *exclusive unionism*.

income approach The method that adds all the *income* generated by the production of *final goods* and *final services* to measure the *gross domestic product*.

income effect A change in the quantity demanded of a product that results from the change in *real income* (*purchasing power*) caused by a change in the product’s *price*.

income elasticity of demand The ratio of the percentage change in the *quantity demanded* of a good to a percentage change in consumer *income*; measures the responsiveness of consumer purchases to income changes.

income inequality The unequal distribution of an economy’s total *income* among *households* or families.

income mobility The extent to which *income* receivers move from one part of the income distribution to another over some period of time.

increasing returns An increase in a *firm*’s output by a larger percentage than the percentage increase in its inputs.

increasing-cost industry An *industry* in which expansion through the entry of new *firms* raises the *prices* firms in the industry must pay for *resources* and therefore increases their production costs.

independent unions U.S. unions that are not affiliated with the *AFL-CIO* or *Change to Win*.

independent variable The variable causing a change in some other (dependent) variable.

index funds *Mutual funds* whose *portfolios* exactly match a stock or bond index (a collection of *stocks* or *bonds* meant to capture the overall behavior of a particular category of investments) such as the Standard & Poor's 500 Index or the Russell 3000 Index.

indifference curve A curve showing the different combinations of two products that yield the same satisfaction or *utility* to a consumer.

indifference map A set of *indifference curves*, each representing a different level of *utility*, that together show the preferences of a consumer.

individual transferable quotas (ITQs) Limits (quotas) set by a government or a fisheries commission on the total number or total weight of a species that an individual fisher can harvest during some particular time period; fishers can sell (transfer) the right to use all or part of their respective individual quotas to other fishers.

industrial regulation The older and more traditional type of regulation in which government is concerned with the *prices* charged and the *services* provided to the public in specific *industries*. Differs from *social regulation*.

industrially advanced countries (IACs) High-income countries such as the United States, Canada, Japan, and the nations of western Europe that have highly developed *market economies* based on large stocks of technologically advanced *capital goods* and skilled labor forces.

inelastic demand Product or resource demand for which the *price elasticity of demand* is less than 1, so that any given percentage change in *price* leads to a smaller percentage change in *quantity demanded*. As a result, quantity demanded is relatively insensitive to (inelastic with respect to) price.

inferior good A *good* or *service* whose consumption declines as *income* rises, *prices* held constant.

inflation A rise in the general level of *prices* in an economy; an increase in an economy's *price level*.

inflation targeting The declaration by a *central bank* of a goal for a specific range of *inflation* in a future year, coupled with *monetary policy* designed to achieve the goal.

inflationary expenditure gap In the *aggregate-expenditures model*, the amount by which the *aggregate expenditures schedule* must shift downward to decrease the *nominal GDP* to its full-employment noninflationary level.

inflexible prices Product *prices* that remain in place (at least for a while) even though *supply* or *demand* has changed; stuck prices or sticky prices.

information technology New and more efficient methods of delivering and receiving information through the use of computers, Wi-Fi networks, wireless phones, and the Internet.

infrastructure The interconnected network of large-scale *capital goods* (such as roads, sewers, electrical grids, railways, ports, and the Internet) needed to operate a technologically advanced economy.

injection An addition of spending into the income-expenditure stream: any increment to *consumption*, *investment*, *government purchases*, or *net exports*.

innovation The first commercially successful introduction of a new product, use of a new method of production, or creation of a new form of business organization.

insider-outsider theory The hypothesis that nominal wages are inflexible downward because *firms* are aware that workers ("insiders") who retain employment during recession may refuse to work cooperatively with previously unemployed workers ("outsiders") who offer to work for less than the current wage.

insurable risk An eventuality for which both the frequency and magnitude of potential losses can be estimated with considerable accuracy. Insurance companies are willing to sell insurance against such risks.

insurance exchanges Government-regulated markets for health insurance in which individuals seeking to purchase health insurance to comply with the *personal mandate* of the *Patient Protection and Affordable Care Act (PPACA)* of 2010 will be able to comparison shop among insurance policies approved by regulators. Each state will have its own exchange.

interest The payment made for the use of (borrowed) *money*.

interest on excess reserves (IOER) *Interest rate* paid by the *Federal Reserve* on bank *excess reserves*.

interest-rate effect The tendency for increases in the *price level* to increase the demand for money, raise interest rates, and, as a result, reduce total spending and real output in the economy (and the reverse for *price-level* decreases).

interest-rate-cost-of-funds curve As it relates to research and development (*R&D*), a curve showing the *interest rate* a *firm* must pay to obtain any particular amount of funds to finance *R&D*.

interindustry competition The competition for sales between the products of one *industry* and the products of another industry.

interlocking directorate A situation where one or more members of the board of directors of a *corporation* are also on the board of directors of a competing corporation; illegal under the *Clayton Act*.

intermediate goods Products that are purchased for resale or further processing or manufacturing.

International Monetary Fund (IMF) The international association of nations that was formed after the Second World War to make loans of foreign monies to nations with temporary *balance of payments deficits* and, until the early 1970s, manage the international system of pegged exchange rates agreed upon at the Bretton Woods conference. It now mainly makes loans to nations facing possible defaults on private and government loans.

invention The conception of a new product or process combined with the first proof that it will work.

inventories Goods that have been produced but remain unsold.

inverse relationship The relationship between two variables that change in opposite directions, for example, product *price* and quantity demanded; a negative relationship.

inverted-U theory (of R&D) The idea that, other things equal, *R&D* expenditures as a percentage of sales rise with *industry* concentration, reach a peak at a *four-firm concentration ratio* of about 50 percent, and then fall as the ratio further increases.

investment In economics, spending for the production and accumulation of *capital* and additions to *inventories*. (For contrast, see *financial investment*.)

investment demand curve A curve that shows the amounts of *investment* demanded by an economy at a series of *real interest rates*.

investment schedule The tendency of *competition* to cause individuals and *firms* to unintentionally but quite effectively promote the interests of society even when each individual or firm is only attempting to pursue its own interests.

invisible hand The tendency of competition to cause individuals and firms to unintentionally but quite effectively promote the interests of society even when each individual or firm is only attempting to pursue its own interests.

kinked-demand curve A *demand curve* that has a flatter slope above the current *price* than below the current price. Applies to a *noncollusive oligopoly* firm if its rivals will match any price decrease but ignore any price increase.

labor Any mental or physical exertion on the part of a human being that is used in the production of a *good* or *service*. One of the four *economic resources*.

labor force Persons 16 years of age and older who are not in institutions and who are employed or are unemployed and seeking work.

labor productivity Total output divided by the quantity of labor employed to produce it; the *average product* of labor or output per hour of work.

labor-force participation rate The percentage of the working-age population that is actually in the *labor force*.

labor-intensive goods Products requiring relatively large amounts of *labor* to produce.

Laffer Curve A curve relating government tax rates and tax revenues and on which a particular tax rate (between zero and 100 percent) maximizes tax revenues.

laissez-faire capitalism A hypothetical *economic system* in which the government's economic role is limited to protecting private property and establishing a legal environment appropriate to the operation of *markets* in which only mutually agreeable transactions would take place between buyers and sellers; sometimes referred to as "pure *capitalism*."

land In addition to the part of the earth's surface not covered by water, this term refers to any and all natural resources ("free gifts of nature") that are used to produce *goods* and *services*. Thus, it includes the oceans, sunshine, coal deposits, forests, the electromagnetic spectrum, and *fisheries*. Note that land is one of the four *economic resources*.

land reform Policy changes aimed at creating a more efficient distribution of land ownership in developing countries. Can involve everything from government purchasing large land estates and dividing the land into smaller farms to consolidating tiny plots of land into larger, more efficient private farms.

land-intensive goods Products requiring relatively large amounts of land to produce.

law of demand The principle that, other things equal, an increase in a product's *price* will reduce the quantity of it demanded, and conversely for a decrease in price.

law of diminishing marginal utility The principle that as a consumer increases the consumption of a *good* or *service*, the *marginal utility* obtained from each additional unit of the good or service decreases.

law of diminishing returns The principle that as successive increments of a variable *resource* are added to a fixed resource, the *marginal product* of the variable resource will eventually decrease.

law of increasing opportunity costs The principle that as the production of a good increases, the *opportunity cost* of producing an additional unit rises.

law of supply The principle that, other things equal, an increase in the *price* of a product will increase the quantity of it supplied, and conversely for a price decrease.

leader countries As it relates to *economic growth*, countries that develop and use the most advanced technologies, which then become available to *follower countries*.

leakage (1) A withdrawal of potential spending from the income-expenditures stream via *saving*, tax payments, or *imports*; (2) a withdrawal that reduces the lending potential of the banking system.

learning by doing Achieving greater *productivity* and lower *average total cost* through gains in knowledge and skill that accompany repetition of a task; a source of *economies of scale*.

least-cost combination of resources The quantity of each *resource* that a *firm* must employ in order to produce a particular output at the lowest total cost; the combination at which the ratio of the *marginal product* of a resource to its *marginal resource cost* (to its *price* if the resource is employed in a competitive market) is the same for the last dollar spent on each of the resources employed.

legal cartel theory of regulation The hypothesis that some *industries* seek regulation or want to maintain regulation so that they may form or maintain a legal *cartel*.

legal immigrant A person who lawfully enters a country for the purpose of residing there.

legal tender Any form of *currency* that by law must be accepted by creditors (lenders) for the settlement of a financial debt; a nation's official currency is legal tender within its own borders.

limited liability rule A law that limits the potential losses that an investor in a *corporation* may suffer to the amount that she paid for her shares in the corporation. Encourages *financial investment* by limiting risk.

liquidity The degree to which an asset can be converted quickly into cash with little or no loss of purchasing power. *Money* is said to be perfectly liquid, whereas other assets have lesser degrees of liquidity.

liquidity trap A situation in a severe *recession* in which the *central bank's* injection of additional reserves into the banking system has little or no additional positive impact on lending, borrowing, *investment*, or *aggregate demand*.

loan guarantees A type of investment *subsidy* in which the government agrees to guarantee (pay off) the money borrowed by a private company to fund investment projects if the private company itself fails to repay the loan.

loanable funds theory of interest The concept that the supply of and demand for *loanable funds* determine the equilibrium rate of *interest*.

lockout A negotiating tactic in which a *firm* forbids its unionized workers to return to work until a new *collective bargaining* agreement is signed; a means of imposing costs (lost wages) on union workers.

logrolling The trading of votes by legislators to secure favorable outcomes on decisions concerning the provision of *public goods* and *quasi-public goods*.

long run (1) In *microeconomics*, a period of time long enough to enable producers of a product to change the quantities of all the resources they employ, so that all resources and costs are variable and no resources or costs are fixed. (2) In *macroeconomics*, a period sufficiently long for *nominal wages* and other input *prices* to change in response to a change in a nation's *price level*.

long-run aggregate supply curve The *aggregate supply* curve associated with a time period in which input *prices* (especially *nominal wages*) are fully responsive to changes in the *price level*.

long-run supply curve As it applies to *macroeconomics*, a *supply curve* for which *price*, but not real output, changes when the *demand curves* shifts; a vertical supply curve that implies fully flexible *prices*.

long-run vertical Phillips Curve The *Phillips Curve* after all *nominal wages* have adjusted to changes in the rate of *inflation*; a line emanating straight upward at the economy's *natural rate of unemployment*.

Lorenz curve A curve showing the distribution of income in an economy. The cumulated percentage of families (income receivers) is measured along the horizontal axis and the cumulated percentage of income is measured along the vertical axis.

loss aversion In *prospect theory*, the property of most people's preferences that the pain generated by losses feels substantially more intense than the pleasure generated by gains.

lump-sum tax A tax that collects a constant amount (the tax revenue of government is the same) at all levels of *GDP*.

M1 The most narrowly defined *money supply*, equal to *currency* in the hands of the public and the *checkable deposits* of commercial banks and *thrift institutions*.

M2 A more broadly defined *money supply*, equal to *M1* plus *non-checkable savings accounts* (including *money market deposit accounts*), small *time deposits* (deposits of less than \$100,000), and individual *money market mutual fund* balances.

macroeconomics The part of *economics* concerned with the performance and behavior of the economy as a whole. Focuses on *economic growth*, the *business cycle*, *interest rates*, *inflation*, and the behavior of major economic *aggregates* such as the household, business, and government sectors.

managed floating exchange rate An *exchange rate* that is allowed to change (float) as a result of changes in *currency* supply and demand but at times is altered (managed) by governments via their buying and selling of particular currencies.

marginal analysis The comparison of *marginal* ("extra" or "additional") *benefits* and *marginal costs*, usually for decision making.

marginal cost (MC) The extra (additional) cost of producing 1 more unit of output; equal to the change in *total cost* divided by the change in output (and, in the short run, to the change in total *variable cost* divided by the change in output).

marginal cost-marginal benefit rule As it applies to *cost-benefit analysis*, the tenet that a government project or program should be expanded to the point where the *marginal cost* and *marginal benefit* of additional expenditures are equal.

marginal product (MP) The additional output produced when 1 additional unit of a resource is employed (the quantity of all other resources employed remaining constant); equal to the change in *total product* divided by the change in the quantity of a resource employed.

marginal productivity theory of income distribution The contention that the distribution of *income* is equitable when each unit of each *resource* receives a *money* payment equal to its *marginal revenue product* (its marginal contribution to the revenue of the *firm* using the unit).

marginal propensity to consume (MPC) The fraction of any change in *disposable income* spent for *consumer goods*; equal to the change in consumption divided by the change in disposable income.

marginal propensity to save (MPS) The fraction of any change in *disposable income* that *households* save; equal to the change in *saving* divided by the change in disposable income.

marginal rate of substitution (MRS) The rate at which a consumer is willing to substitute one good for another (from a given combination of goods) and remain equally satisfied (have the same *total utility*); equal to the slope of a consumer's *indifference curve* at each point on the curve.

marginal resource cost (MRC) The amount by which the total cost of employing a *resource* increases when a *firm* employs 1 additional unit of the resource (the quantity of all other resources employed remaining constant); equal to the change in the *total cost* of the resource divided by the change in the quantity of the resource employed.

marginal revenue The change in *total revenue* that results from the sale of 1 additional unit of a *firm's* product; equal to the change in total revenue divided by the change in the quantity of the product sold.

marginal revenue product (MRP) The change in a firm's *total revenue* when it employs 1 additional unit of a *resource* (the quantity of all other resources employed remaining constant); equal to the change in *total revenue* divided by the change in the quantity of the resource employed.

marginal revenue productivity (See *marginal revenue product*.)

marginal tax rate The *tax rate* paid on an additional dollar of *income*.

marginal utility The extra *utility* a consumer obtains from the consumption of 1 additional unit of a *good* or *service*; equal to the change in *total utility* divided by the change in the quantity consumed.

market Any institution or mechanism that brings together buyers (demanders) and sellers (suppliers) of a particular *good* or *service*.

market failure The inability of a *market* to bring about the allocation of *resources* that best satisfies the wants of society; in particular, the overallocation or underallocation of resources to the production

of a particular *good* or *service* because of *externalities* or informational problems or because markets do not provide desired *public goods*.

market portfolio The portfolio consisting of every financial asset (including every *stock* and *bond*) traded in the financial markets. Used to calculate *beta* (a measure of the degree of riskiness) for specific stocks, bonds, and mutual funds.

market structure The characteristics of an *industry* that define the likely behavior and performance of its *firms*. The primary characteristics are the number of firms in the industry, whether they are selling a *differentiated product*, the ease of entry, and how much control firms have over output prices. The most commonly discussed market structures are *pure competition*, *monopolistic competition*, *oligopoly*, *pure monopoly*, and *monopsony*.

market system (1) An *economic system* in which individuals own most *economic resources* and in which *markets* and *prices* serve as the dominant coordinating mechanism used to allocate those resources; *capitalism*. Compare with *command system*. (2) All the product and resource markets of a *market economy* and the relationships among them.

marketing loan program A federal farm subsidy under which certain farmers can receive a loan (on a per-unit-of-output basis) to plant a crop and then, depending on the harvest *price* of the crop, either pay back the loan with interest or keep the loan proceeds while forfeiting their harvested crop to the lender.

median-voter model The theory that under majority rule the median (middle) voter will be in the dominant position to determine the outcome of an election.

Medicaid A federal program that helps finance the medical expenses of individuals covered by the *Supplemental Security Income (SSI)* and *Temporary Assistance for Needy Families (TANF)* programs.

Medicare A federal program that provides for (1) compulsory hospital insurance for senior citizens, (2) low-cost voluntary insurance to help older Americans pay physicians' fees, and (3) subsidized insurance to buy prescription drugs. Financed by *payroll taxes*.

medium of exchange Any item sellers generally accept and buyers generally use to pay for a *good* or *service*; *money*; a convenient means of exchanging goods and *services* without engaging in *barter*.

mental accounting The tendency people have to create separate "mental boxes" (or "accounts") in which they deal with particular financial transactions in isolation rather than dealing with them as part of an overall decision-making process that would consider how to best allocate their limited budgets across all possible options by using the *utility-maximizing rule*.

menu costs The reluctance of *firms* to cut *prices* during *recessions* (that they think will be short-lived) because of the costs of altering and communicating their price reductions; named after the cost associated with printing new menus at restaurants.

microcredit Anti-poverty programs that lend small amounts of money to poor entrepreneurs.

microeconomics The part of economics concerned with (1) decision making by individual units such as a *household*, a *firm*, or an *industry* and (2) individual markets, specific *goods* and *services*, and product and resource *prices*.

microfinance The provision of small loans and other financial services to low-income *entrepreneurs* and small-business owners in *developing countries*.

Microsoft case A 2002 antitrust case in which Microsoft was found guilty of violating the *Sherman Act* by engaging in a series of unlawful activities designed to maintain its *monopoly* in operating systems for personal computers; as a remedy the company was prohibited from engaging in a set of specific anticompetitive business practices.

midpoint formula A method for calculating *price elasticity of demand* or *price elasticity of supply* that averages the starting and ending *prices* and quantities when computing percentages.

minimum efficient scale (MES) The lowest level of output at which a *firm* can minimize long-run *average total cost*.

minimum wage The lowest *wage* that employers may legally pay for an hour of work.

modern economic growth The historically recent phenomenon in which nations for the first time have experienced sustained increases in *real GDP per capita*.

monetarism The macroeconomic view that the main cause of changes in aggregate output and the *price level* is fluctuations in the *money supply*; espoused by advocates of a *monetary rule*.

monetary multiplier The multiple of its *excess reserves* by which the banking system can expand *checkable deposits* and thus the *money supply* by making new loans (or buying *securities*); equal to 1 divided by the *reserve requirement*.

monetary policy A central bank's changing of the *money supply* to influence *interest rates* and assist the economy in achieving *price-level stability*, *full employment*, and *economic growth*.

monetary rule (1) A set of guidelines to be followed by a *central bank* that wishes to adjust monetary policy over time to achieve goals such as promoting *economic growth*, encouraging *full employment*, and maintaining a stable *price level*. (2) The guidelines for conducting monetary policy suggested by *monetarism*. As traditionally formulated, the *money supply* should be expanded each year at the same annual rate as the potential rate of growth of *real gross domestic product*; the supply of money should be increased steadily between 3 and 5 percent per year. (Also see *Taylor rule*.)

money Any item that is generally acceptable to sellers in exchange for *goods* and *services*.

money market deposit accounts (MMDAs) Interest-bearing accounts offered by *commercial banks* and *thrift institutions* that invest deposited funds into a variety of short-term *securities*. Depositors may write checks against their balances, but there are minimum-balance requirements as well as limits on the frequency of check writing and withdrawals.

money market mutual funds (MMMFs) *Mutual funds* that invest in short-term *securities*. Depositors can write checks in minimum amounts or more against their accounts.

monopolistic competition A *market structure* in which many *firms* sell a *differentiated product*, entry is relatively easy, each firm has some control over its product *price*, and there is considerable *nonprice competition*.

monopsony A *market structure* in which there is only a single buyer of a good, *service*, or *resource*.

moral hazard problem The possibility that individuals or institutions will change their behavior as the result of a contract or agreement. Example: A bank whose deposits are insured against losses may make riskier loans and investments.

mortgage-backed securities *Bonds* that represent claims to all or part of the monthly mortgage payments from the pools of mortgage loans made by lenders to borrowers to help them purchase residential property.

MR = MC rule The principle that a *firm* will maximize its profit (or minimize its losses) by producing the output at which *marginal revenue* and *marginal cost* are equal, provided *product price* is equal to or greater than *average variable cost*.

MRP = MRC rule The principle that to maximize profit (or minimize losses), a *firm* should employ the quantity of a resource at which its *marginal revenue product* (MRP) is equal to its *marginal resource cost* (MRC), the latter being the wage rate in a purely competitive labor market.

multiple counting Wrongly including the value of *intermediate goods* in the *gross domestic product*; counting the same *good* or *service* more than once.

multiplier The ratio of a change in *equilibrium GDP* to the change in *investment* or in any other component of *aggregate expenditures* or *aggregate demand*; the number by which a change in any such component must be multiplied to find the resulting change in *equilibrium GDP*.

mutual funds *Portfolios of stocks and bonds* selected and purchased by mutual fund companies, which finance the purchases by pooling money from thousands of individual investors; includes both *index funds* as well as *actively managed funds*. Fund returns (profits or losses) pass through to each fund's investors.

mutual interdependence A situation in which a change in *price strategy* (or in some other strategy) by one *firm* will affect the sales and profits of another firm (or other firms). Any firm that makes such a change can expect its rivals to react to the change.

myopia Refers to the difficulty human beings have with conceptualizing the more distant future. Leads to decisions that overly favor present and near-term options at the expense of more distant future possibilities.

Nash equilibrium The situation that occurs in some *simultaneous games* wherein every player is playing his or her *dominant strategy* at the same time and thus no player has any reason to change behavior.

national health insurance A program in which a nation's government provides a basic package of health care to all citizens at no direct charge or at a low cost-sharing level. Financing is out of general *tax revenues*.

national income Total *income* earned by *resource suppliers* for their contributions to *gross domestic product* plus *taxes on production and imports*; the sum of wages and salaries, *rent*, *interest*, *profit*, *proprietors' income*, and such taxes.

national income accounting The techniques used to measure the overall production of a country's economy as well as other related variables.

National Labor Relations Act (NLRA) The basic labor-relations law in the United States. Defines the legal rights of unions and management and identifies unfair union and management labor practices; established the *National Labor Relations Board*. Often referred to as the Wagner Act, after the legislation's sponsor, New York Senator Robert F. Wagner.

National Labor Relations Board (NLRB) The board established by the *National Labor Relations Act* of 1935 to investigate unfair labor practices, issue *cease-and-desist orders*, and conduct elections among employees to determine if they wish to be represented by a *labor union*.

natural monopoly An *industry* in which *economies of scale* are so great that a single *firm* can produce the industry's product at a lower average total cost than would be possible if more than one firm produced the product.

natural rate of unemployment (NRU) The *full-employment rate of unemployment*; the *unemployment rate* occurring when there is no cyclical unemployment and the economy is achieving its *potential output*; the unemployment rate at which actual *inflation* equals expected inflation.

near-money Financial *assets* that are not themselves a *medium of exchange* but that have extremely high *liquidity* and thus can be readily converted into *money*. Includes noncheckable *savings accounts*, *time deposits*, and short-term *U.S. government securities* plus savings bonds.

negative self-selection As it relates to international migration, the idea that those who choose to move to another country have poorer *wage opportunities* in the origin country than those with similar skills who choose not to *emigrate*.

negative-sum game In *game theory*, a game in which the gains (+) and losses (–) add up to some amount less than zero; one party's losses exceed the other party's gains. A strategic interaction (*game*) between two or more parties (players) in which the winners' gains are less than the losers' losses so that the gains and losses sum to a negative number.

neoclassical economics The dominant and conventional branch of economic theory that attempts to predict human behavior by building economic models based on simplifying assumptions about people's motives and capabilities. These include that people are fundamentally *rational*; motivated almost entirely by *self-interest*; good at math; and unaffected by *heuristics*, *time inconsistency*, and *self-control problems*.

net benefits The total benefits of some activity or policy less the total costs of that activity or policy.

net domestic product (NDP) *Gross domestic product* less the part of the year's output that is needed to replace the *capital goods* worn out in producing the output; the nation's total output available for consumption or additions to the *capital stock*.

net exports (X_n) *Exports* minus *imports*.

net private domestic investment *Gross private domestic investment* less *consumption of fixed capital*; the addition to the nation's stock of *capital* during a year.

network effects Increases in the value of a product to each user, including existing users, as the total number of users rises.

new classical economics The theory that, although unanticipated *price-level* changes may create macroeconomic instability in the short run, the economy will return to and stabilize at the full-employment level of domestic output in the long run because *prices* and *wages* adjust automatically to correct movements away from the full-employment output level.

nominal gross domestic product (GDP) *GDP* measured in terms of the *price level* at the time of measurement; *GDP* not adjusted for *inflation*.

nominal income The number of dollars received by an individual or group for its *resources* during some period of time.

nominal interest rate The *interest rate* expressed in terms of annual amounts currently charged for *interest* and not adjusted for *inflation*.

nominal wage The amount of *money* received by a worker per unit of time (hour, day, etc.); money wage.

noncash transfer A *government transfer payment* in the form of *goods* and *services* rather than *money*, for example, food stamps, housing assistance, and job training; also called *in-kind transfers*.

noncompeting groups Collections of workers who do not compete with each other for employment because the skill and training of the workers in one group are substantially different from those of the workers in other groups.

nondiversifiable risk Investment *risk* that investors are unable to reduce via *diversification*; also called systemic risk.

nonurable good A *consumer good* with an expected life (use) of less than three years.

nonexcludability The inability to keep nonpayers (free riders) from obtaining benefits from a certain good; a characteristic of a *public good*.

nonprice competition Competition based on distinguishing one's product by means of *product differentiation* and then *advertising* the distinguished product to consumers.

nonrenewable natural resource Things such as oil, natural gas, and metals, that are either in actual fixed supply or that renew so slowly as to be in virtual fixed supply when viewed from a human time perspective.

nonrivalry The idea that one person's benefit from a certain *good* does not reduce the benefit available to others; a characteristic of a *public good*.

nontariff barriers (NTBs) All barriers other than *protective tariffs* that nations erect to impede international trade, including *import quotas*, licensing requirements, unreasonable product-quality standards, unnecessary bureaucratic detail in customs procedures, and so on.

normal good A *good* or *service* whose consumption increases when *income* increases and falls when income decreases, *price* remaining constant.

normal profit The payment made by a *firm* to obtain and retain *entrepreneurial ability*; the minimum *income* that entrepreneurial ability must receive to induce *entrepreneurs* to provide their entrepreneurial ability to a firm; the level of *accounting profit* at which a firm generates an *economic profit* of zero after paying for entrepreneurial ability.

normative economics The part of economics involving value judgments about what the economy should be like; focused on which economic goals and policies should be implemented; policy economics.

North American Free Trade Agreement (NAFTA) The 1993 treaty that established an international free-trade zone composed of Canada, Mexico, and the United States.

occupational licensing The laws of state or local governments that require that a worker satisfy certain specified requirements and obtain a license from a licensing board before engaging in a particular occupation.

occupational segregation The crowding of women or minorities into less desirable, lower-paying occupations.

official reserves Foreign *currencies* owned by the central bank of a nation.

offshoring The practice of shifting work previously done by domestic workers to workers located abroad.

Okun's law The generalization that any 1-percentage-point rise in the *unemployment rate* above the *full-employment rate of unemployment* is associated with a rise in the *negative GDP gap* by 2 percent of *potential output* (potential *GDP*).

oligopoly A *market structure* in which a few *firms* sell either a *standardized* or *differentiated product*, into which entry is difficult, in which the firm has limited control over product *price* because of *mutual interdependence* (except when there is collusion among firms), and in which there is typically *nonprice competition*.

one-time game A strategic interaction (*game*) between two or more parties (players) that all parties know will take place only once.

open shop A place of employment in which the employer may hire nonunion workers and in which the workers need not become members of a *labor union*.

open-market operations The purchases and sales of U.S. government *securities* that the *Federal Reserve System* undertakes in order to influence *interest rates* and the *money supply*; one method by which the *Federal Reserve* implements *monetary policy*.

opportunity cost The amount of other products that must be forgone or sacrificed to produce a unit of a product.

opportunity-cost ratio An equivalency showing the number of units of two products that can be produced with the same *resources*; the equivalency 1 corn \equiv 3 olives shows that the resources required to produce 3 units of olives must be shifted to corn production to produce 1 unit of corn.

optimal amount of R&D The level of *R&D* at which the *marginal benefit* and *marginal cost* of *R&D* expenditures are equal.

optimal reduction of an externality The reduction of a *negative externality* such as pollution to the level at which the *marginal benefit* and *marginal cost* of reduction are equal.

other-things-equal assumption The assumption that factors other than those being considered are held constant; *ceteris paribus* assumption.

output effect The possibility that when the *price* of the first of a pair of *substitute resources* falls, the *quantity demanded* of both

resources will rise because the reduction in the price of the first resource so greatly reduces production costs that the volume of output created with the two resources increases by so much that the quantity demanded of the second resource increases even after accounting for the *substitution effect*. (See the second definition listed in the entry for *substitution effect*.)

paradox of thrift The seemingly self-contradictory but possibly true statement that increased *saving* may be both good and bad for the economy. It is always good in the long run when matched with increased *investment* spending, but may be bad in the short run if there is a *recession* because it reduces spending on *goods* and *services*. If the increased savings are not translated into increased investment, then the fall in consumption spending will not be made up for by an increase in investment. The overall result will be a decrease in output and employment. If the decline in *GDP* is severe enough, the attempt to save more will actually lead to less overall savings because the higher rate of saving will be applied to a smaller *national income*. Attempts by *households* to save more during a recession may simply worsen the recession and result in less saving.

paradox of voting A situation where paired-choice voting by majority rule fails to provide a consistent ranking of society's preferences for *public goods* or *public services*.

parity concept The idea that year after year the sale of a specific output of a farm product should enable a farmer to purchase a constant amount of nonagricultural *goods* and *services*.

parity ratio The ratio of the *price* received by farmers from the sale of an agricultural commodity to the prices of other goods paid by them; usually expressed as a percentage; used as a rationale for *price supports*.

partnership An unincorporated *firm* owned and operated by two or more persons.

passively managed funds *Mutual funds* whose *portfolios* are not regularly updated by a fund manager attempting to generate high returns. Rather, once an initial portfolio is selected, it is left unchanged so that investors receive whatever return that unchanging portfolio subsequently generates. *Index funds* are a type of passively managed fund.

patent An exclusive right given to inventors to produce and sell a new product or machine for 20 years from the time of patent application.

Patient Protection and Affordable Care Act (PPACA) A major health care law passed by the federal government in 2010. Major provisions include an individual health insurance mandate, a ban on insurers refusing to accept patients with preexisting conditions, and federal (rather than state) regulation of health insurance policies.

payroll tax A *tax* levied on employers of labor equal to a percentage of all or part of the *wages* and salaries paid by them and on employees equal to a percentage of all or part of the *wages* and salaries received by them.

peak The point in a *business cycle* at which business activity has reached a temporary maximum; the point at which an *expansion* ends and a *recession* begins. At the peak, the economy is near or at *full employment* and the level of real output is at or very close to the economy's capacity.

per se violations Collusive actions, such as attempts by *firms* to fix *prices* or divide a market, that are violations of the *antitrust laws*, even if the actions themselves are unsuccessful.

per-unit production cost The average production cost of a particular level of output; total input cost divided by units of output.

percentage rate of return The percentage gain or loss, relative to the buying *price*, of an *economic investment* or *financial investment* over some period of time.

perfectly elastic demand Product or *resource* demand in which *quantity demanded* can be of any amount at a particular product or resource *price*; graphs as a horizontal *demand curve*.

perfectly inelastic demand Product or *resource* demand in which *price* can be of any amount at a particular quantity of the product or resource that is demanded; when the *quantity demanded* does not respond to a change in price; graphs as a vertical *demand curve*.

personal consumption expenditures (C) The expenditures of *households* for both durable and nondurable *consumer goods*.

personal income (PI) The earned and unearned *income* available to resource suppliers and others before the payment of personal *taxes*.

personal income tax A *tax* levied on the taxable income of individuals, *households*, and unincorporated *firms*.

personal mandate The requirement under the *Patient Protection and Affordable Care Act (PPACA)* of 2010 that all U.S. citizens and legal residents purchase health insurance unless they are already covered by employer-sponsored health insurance or government-sponsored health insurance (*Medicaid* or *Medicare*).

Phillips Curve A curve showing the relationship between the *unemployment rate* (on the horizontal axis) and the annual rate of increase in the *price level* (on the vertical axis).

Pigovian tax A *tax* or charge levied on the production of a product that generates *negative externalities*. If set correctly, the tax will precisely offset the overallocation (overproduction) generated by the negative externality.

planned investment The amount that *firms* plan or intend to invest.

political business cycle Fluctuations in the economy caused by the alleged tendency of Congress to destabilize the economy by reducing taxes and increasing government expenditures before elections and to raise taxes and lower expenditures after elections.

political corruption The unlawful misdirection of governmental resources or actions that occurs when government officials abuse their entrusted powers for personal gain. (Also see *corruption*.)

portfolio A specific collection of *stocks*, *bonds*, or other *financial investments* held by an individual or a *mutual fund*.

positive economics The analysis of facts or data to establish scientific generalizations about economic behavior.

positive-sum game In *game theory*, a game in which the gains (+) and losses (–) add up to more than zero; one party's gains exceed the other party's losses. A strategic interaction (*game*) between two or more parties (players) in which the winners' gains exceed the losers' losses so that the gains and losses sum to something positive.

potential output The real output (*GDP*) an economy can produce when it fully employs its available resources.

poverty rate The percentage of the population with incomes below the official poverty income levels that are established by the federal government.

precommitments Actions taken ahead of time that make it difficult for the future self to avoid doing what the present self desires. See *time inconsistency* and *self-control problems*.

preferred provider organization (PPO) An arrangement in which doctors and hospitals agree to provide health care to insured individuals at rates negotiated with an insurer.

present value Today's value of some amount of *money* that is to be received sometime in the future.

price ceiling A legally established maximum *price* for a *good*, or *service*. Normally set at a price below the *equilibrium price*.

price discrimination The selling of a product to different buyers at different *prices* when the price differences are not justified by differences in cost.

price elasticity of demand The ratio of the percentage change in *quantity demanded* of a product or *resource* to the percentage change in its *price*; a measure of the responsiveness of buyers to a change in the price of a product or resource.

price elasticity of supply The ratio of the percentage change in *quantity supplied* of a product or *resource* to the percentage change in its *price*; a measure of the responsiveness of producers to a change in the price of a product or resource.

price floor A legally established minimum *price* for a *good*, or *service*. Normally set at a price above the *equilibrium price*.

price index An index number that shows how the weighted-average *price* of a "market basket" of goods changes over time relative to its price in a specific *base year*.

price leadership An informal method that *firms* in an *oligopoly* may employ to set the *price* of their product: One firm (the leader) is the first to announce a change in price, and the other firms (the followers) soon announce identical or similar changes.

price loss coverage A form of *crop insurance* that pays participating farmers if the market price of their output falls below a predetermined value.

price support The term used to refer to *price floors* applied to *farm commodities*; the minimum *price* that the government allows farmers to receive for farm commodities like wheat or corn.

price taker A seller (or buyer) that is unable to affect the *price* at which a product or *resource* sells by changing the amount it sells (or buys).

price war Successive, competitive, and continued decreases in the *prices* charged by *firms* in an oligopolistic *industry*. At each stage of the price war, one *firm* lowers its price below its rivals' price, hoping to increase its sales and revenues at its rivals' expense. The war ends when the price decreases cease.

price-level surprises Unanticipated changes in the *price level*.

prime interest rate The benchmark *interest rate* that banks use as a reference point for a wide range of loans to businesses and individuals.

principal-agent problem (1) At a *firm*, a conflict of interest that occurs when agents (workers or managers) pursue their own objectives to the detriment of the principals' (stockholders') goals. (2) In *public choice theory*, a conflict of interest that arises when elected officials (who are the agents of the people) pursue policies that are in their own interests rather than policies that would be in the better interests of the public (the principals).

principle of comparative advantage The proposition that an individual, region, or nation will benefit if it specializes in producing goods for which its own *opportunity costs* are lower than the opportunity costs of a trading partner, and then exchanging some of the products in which it specializes for other desired products produced by others.

private good A *good*, or *service* that is individually consumed and that can be profitably provided by privately owned *firms* because they can exclude nonpayers from receiving the benefits.

private property The right of private persons and *firms* to obtain, own, control, employ, dispose of, and bequeath *land*, *capital*, and other property.

probability-weighted average Each of the possible future rates of return from an investment multiplied by its respective probability (expressed as a decimal) of happening.

process innovation The development and use of new or improved production or distribution methods.

producer surplus The difference between the actual *price* a producer receives (or producers receive) and the minimum acceptable price; the triangular area above the *supply curve* and below the market price.

product differentiation A strategy in which one *firm's* product is distinguished from competing products by means of its design, related *services*, quality, location, or other attributes (except *price*).

product innovation The development and sale of a new or improved product (or service).

product market A market in which products are sold by *firms* and bought by *households*.

production possibilities curve A curve showing the different combinations of two goods or *services* that can be produced in a *full-employment, full-production* economy where the available supplies of *resources* and technology are fixed.

productive efficiency The production of a *good* in the least costly way; occurs when production takes place at the output at which *average total cost* is a minimum and *marginal product* per dollar's worth of input is the same for all inputs.

productivity A measure of average output or real output per unit of input. For example, the productivity of labor is determined by dividing real output by hours of work.

profit-maximizing combination of resources The quantity of each *resource* a *firm* must employ to maximize its *profit* or minimize its loss; the combination of resource inputs at which the *marginal revenue product* of each resource is equal to its *marginal resource cost* (to its *price* if the resource is employed in a competitive market).

progressive tax At the individual level, a *tax* whose *average tax rate* increases as the taxpayer's *income* increases. At the national level, a *tax* for which the *average tax rate* (= tax revenue/*GDP*) rises with *GDP*.

property tax A tax on the value of property (*capital, land, stocks* and *bonds*, and other *assets*) owned by *firms* and *households*.

proportional tax At the individual level, a tax whose *average tax rate* remains constant as the taxpayer's *income* increases or decreases. At the national level, a tax for which the *average tax rate* (= tax revenue/GDP) remains constant as *GDP* rises or falls.

prospect theory A *behavioral economics* theory of preferences having three main features: (1) people evaluate options on the basis of whether they generate gains or losses relative to the *status quo*; (2) gains are subject to *diminishing marginal utility*, while losses are subject to *diminishing marginal disutility*; and (3) people are prone to *loss aversion*.

protective tariff A *tariff* designed to shield domestic producers of a *good* or *service* from the competition of foreign producers.

public assistance programs Government programs that pay benefits to those who are unable to earn *income* (because of permanent disabilities or because they have very low income and dependent children); financed by general *tax* revenues and viewed as public charity (rather than earned rights).

public choice theory The economic analysis of government decision making, politics, and elections.

public debt The total amount owed by the federal government to the owners of government *securities*; equal to the sum of past government *budget deficits* less government *budget surpluses*.

public good A *good* or *service* that is characterized by *nonrivalry* and *nonexcludability*. These characteristics typically imply that no private *firm* can break even when attempting to provide such products. As a result, they are often provided by governments, who pay for them using general *tax* revenues.

public interest theory of regulation The presumption that the purpose of the regulation of an *industry* is to protect the public (consumers) from abuse of the power possessed by *natural monopolies*.

public investments Government expenditures on public capital (such as roads, highways, bridges, mass-transit systems, and electric power facilities) and on *human capital* (such as education, training, and health).

purchasing-power-parity theory The idea that if countries have *flexible exchange rates* (rather than *fixed exchange rates*), the exchange rates between national currencies will adjust to equate the purchasing power of various currencies. In particular, the exchange rate between any two national currencies will adjust to reflect the *price-level* differences between the two countries.

pure competition A *market structure* in which a very large number of *firms* sells a *standardized product*, into which entry is very easy, in which the individual seller has no control over the product *price*, and in which there is no nonprice competition; a market characterized by a very large number of buyers and sellers.

pure monopoly A *market structure* in which one *firm* sells a unique product, into which entry is blocked, in which the single firm has considerable control over product *price*, and in which *nonprice competition* may or may not be found.

pure profit (See *economic profit*.)

pure rate of interest The hypothetical *interest rate* that is completely *risk-free* and not subject to market imperfections; the

hypothetical interest rate that would only compensate investors for *time preference*.

purely competitive labor market A *resource market* in which many *firms* compete with one another in hiring a specific kind of *labor*, numerous equally qualified workers supply that labor, and no one controls the market *wage rate*.

quantitative easing (QE) An *open-market operation* in which *bonds* are purchased by a *central bank* in order to increase the quantity of *excess reserves* held by *commercial banks* and thereby (hopefully) stimulate the economy by increasing the amount of lending undertaken by commercial banks; undertaken when interest rates are near zero and, consequently, it is not possible for the central bank to further stimulate the economy with lower interest rates due to the *zero lower bound problem*.

quasi-public good A *good* or *service* to which *excludability* could apply but that has such a large *positive externality* that government sponsors its production to prevent an underallocation of resources.

rational Behaviors and decisions that maximize a person's chances of achieving his or her goals. See *rational behavior*.

rational behavior Human behavior based on comparison of *marginal costs* and *marginal benefits*; behavior designed to maximize *total utility*. See *rational*.

rational expectations theory The hypothesis that *firms* and *households* expect monetary and fiscal policies to have certain effects on the economy and (in pursuit of their own self-interests) take actions that make these policies ineffective.

real GDP (See *real gross domestic product*.)

real GDP per capita *Inflation*-adjusted output per person; *real GDP*/population.

real gross domestic product (GDP) *Gross domestic product* adjusted for *inflation*; gross domestic product in a year divided by the *GDP price index* for that year, the index expressed as a decimal.

real income The amount of *goods* and *services* that can be purchased with *nominal income* during some period of time; nominal income adjusted for *inflation*.

real interest rate The *interest rate* expressed in dollars of constant value (adjusted for *inflation*) and equal to the *nominal interest rate* less the expected rate of inflation.

real wage The amount of *goods* and *services* a worker can purchase with his or her *nominal wage*; the *purchasing power* of the *nominal wage*.

real-balances effect The tendency for increases in the *price level* to lower the real value (or *purchasing power*) of financial *assets* with fixed *money* value and, as a result, to reduce total spending and real output, and conversely for decreases in the *price level*.

real-business-cycle theory A theory that *business cycles* result from changes in *technology* and *resource* availability, which affect *productivity* and thus increase or decrease long-run *aggregate supply*.

recession A period of declining *real GDP*, accompanied by lower *real income* and higher *unemployment*.

recessionary expenditure gap The amount by which the *aggregate expenditures schedule* must shift upward to increase *real GDP* to its full-employment, noninflationary level.

regressive tax At the individual level, a *tax* whose *average tax rate* decreases as the taxpayer's *income* increases. At the national level, a *tax* for which the *average tax rate* (= tax revenue/*GDP*) falls as *GDP* rises.

regulatory agency An agency, commission, or board established by the federal government or a state government to control the *prices* charged and the *services* offered by a *natural monopoly* or *public utility*.

regulatory capture The situation that occurs when a governmental *regulatory agency* ends up being controlled by the industry that it is supposed to be regulating.

remittances Payments by *immigrants* to family members and others located in the immigrants' home countries.

renewable natural resources Things such as forests, water in reservoirs, and wildlife that are capable of growing back or building back up (renewing themselves) if they are harvested at moderate rates.

rent-seeking behavior The actions by persons, *firms*, or unions to gain special benefits from government at the taxpayers' or someone else's expense.

repeated game A strategic interaction (*game*) between two or more parties (players) that all parties know will take place repeatedly.

replacement rate The *total fertility rate* necessary to offset deaths in a country and thereby keep the size of its population constant (without relying on immigration). For most countries, a total fertility rate of about 2.1 births per woman per lifetime.

repo A repurchase agreement (or "repo") is a short-term money loan made by a lender to a borrower that is collateralized with *bonds* pledged by the borrower. The name *repo* refers to how the lender would view the transaction. The same transaction when viewed from the perspective of the borrower would be called a *reverse repo*.

required reserves The funds that each *commercial bank* and *thrift institution* must deposit with its local *Federal Reserve Bank* (or hold as *vault cash*) to meet the legal *reserve requirement*; a fixed percentage of each bank's or thrift's *checkable deposits*.

reserve ratio The fraction of *checkable deposits* that each *commercial bank* or *thrift institution* must hold as reserves at its local *Federal Reserve Bank* or in its own bank vault; also called the *reserve requirement*.

residual claimant In a market system, the economic agent who receives (is claimant to) whatever profit or loss remains (is residual) at a firm after all other *input* providers have been paid. The residual is compensation for providing the economic input of *entrepreneurial ability* and flows to the firm's owners.

resource market A market in which *households* sell and *firms* buy *resources* or the services of resources.

restrictive monetary policy *Federal Reserve System* actions to reduce the *money supply*, increase *interest rates*, and reduce *inflation*; a tight money policy.

revenue tariff A *tariff* designed to produce *income* for the federal government.

reverse repo A reverse repurchase agreement (or "reverse repo") is a short-term money loan that the borrower obtains by pledging *bonds* as collateral. The name *reverse repo* refers to how the borrower would view the transaction. The same transaction when viewed by the lender would be called a *repo*.

right-to-work law A state law (in 23 states) that makes it illegal to require that a worker join a *labor union* in order to retain his or her job; laws that make *union shops* and *agency shops* illegal.

risk The uncertainty as to the future returns of a particular *financial investment* or *economic investment*.

risk premium The *interest rate* above the *risk-free* interest rate that must be paid and received to compensate a lender or investor for *risk*.

risk-free interest rate The *interest rate* earned on short-term U.S. government *bonds*.

rivalry (1) The characteristic of a *private good*, the consumption of which by one party excludes other parties from obtaining the benefit; (2) the attempt by one *firm* to gain strategic advantage over another firm to enhance market share or *profit*.

rule of 70 A method for determining the number of years it will take for some measure to double, given its annual percentage increase. Example: To determine the number of years it will take for the *price level* to double, divide 70 by the annual rate of *inflation*.

rule of reason The rule stated and applied in the *U.S. Steel case* that only combinations and contracts unreasonably restraining trade are subject to actions under the antitrust laws and that size and possession of *monopoly* power are not by themselves illegal. Compare with *per se violation*.

sales tax A *tax* levied on the cost (at retail) of a broad group of products.

saving *Disposable income* not spent for *consumer goods*; equal to *disposable income* minus *personal consumption expenditures*; saving is a flow. Compare with *savings*.

saving schedule A table of numbers that shows the amounts *households* plan to save (plan not to spend for *consumer goods*), at different levels of *disposable income*.

savings account A deposit in a *commercial bank* or *thrift institution* on which *interest* payments are received; generally used for *saving* rather than daily transactions; a component of the *M2 money supply*.

scarcity The limits placed on the amounts and types of *goods* and *services* available for consumption as the result of there being only limited *economic resources* from which to produce output; the fundamental economic constraint that creates *opportunity costs* and that necessitates the use of *marginal analysis* (*cost-benefit analysis*) to make optimal choices.

scientific method The procedure for the systematic pursuit of knowledge involving the observation of facts and the formulation and testing of hypotheses to obtain theories, principles, and laws.

securitization The process of aggregating many individual financial debts, such as mortgages or student loans, into a pool and then issuing new *securities* (typically *bonds*) backed by the pool. The holders of the new securities are entitled to receive the debt payments made on the individual financial debts in the pool.

Security Market Line (SML) A line that shows the *average expected rate of return* of all *financial investments* at each level of *nondiversifiable risk*, the latter measured by *beta*.

self-control problems Refers to the difficulty people have in sticking with earlier plans and avoiding suboptimal decisions when finally confronted with a particular decision-making situation. A manifestation of *time inconsistency* and potentially avoidable by using *precommitments*.

self-interest That which each *firm*, property owner, worker, and consumer believes is best for itself and seeks to obtain.

self-selection As it relates to international migration, the idea that those who choose to move to a new country tend to have greater motivation for economic gain or greater willingness to sacrifice current consumption for future consumption than those with similar skills who choose to remain at home.

sequential game A strategic interaction (*game*) between two or more parties (players) in which each party moves (makes a decision) in a predetermined order (sequence).

service An (intangible) act or use for which a consumer, *firm*, or government is willing to pay.

Sherman Act The federal antitrust law of 1890 that makes *monopoly* and conspiracies to restrain trade criminal offenses.

shocks Sudden, unexpected changes in *demand* (or *aggregate demand*) or supply (or *aggregate supply*).

short run (1) In *microeconomics*, a period of time in which producers are able to change the quantities of some but not all of the *resources* they employ; a period in which some resources (usually *plant*) are fixed and some are variable. (2) In *macroeconomics*, a period in which *nominal wages* and other input *prices* do not change in response to a change in the *price level*.

short-run aggregate supply curve An *aggregate supply* curve relevant to a time period in which input *prices* (particularly *nominal wages*) do not change in response to changes in the *price level*.

short-run supply curve A *supply curve* that shows the quantity of a product a *firm* in a purely competitive *industry* will offer to sell at various *prices* in the *short run*; the portion of the firm's short-run *marginal cost curve* that lies above its *average-variable-cost* curve.

shortage The amount by which the *quantity demanded* of a product exceeds the *quantity supplied* at a particular (below-equilibrium) *price*.

simultaneous consumption The same-time derivation of *utility* from some product by a large number of consumers.

simultaneous game A strategic interaction (*game*) between two or more parties (players) in which every player moves (makes a decision) at the same time.

single-tax movement The political efforts by followers of Henry George (1839–1897) to impose a single *tax* on the value of land and eliminate all other taxes.

skill transferability The ease with which people can shift their work talents from one job, region, or country to another job, region, or country.

slope of a straight line The ratio of the vertical change (the rise or fall) to the horizontal change (the run) between any two points on a

straight line. The slope of an upward-sloping line is positive, reflecting a direct relationship between two variables; the slope of a downward-sloping line is negative, reflecting an inverse relationship between two variables.

Smoot-Hawley Tariff Act Legislation passed in 1930 that established very high *tariffs*. Its objective was to reduce *imports* and stimulate the domestic economy, but it resulted only in retaliatory tariffs by other nations.

social insurance programs Programs that replace the earnings lost when people retire or are temporarily unemployed, that are financed by payroll *taxes*, and that are viewed as earned rights (rather than charity).

social regulation Regulation in which government is concerned with the conditions under which *goods* and *services* are produced, their physical characteristics, and the impact of their production on society. Differs from *industrial regulation*.

Social Security The social insurance program in the United States financed by federal *payroll taxes* on employers and employees and designed to replace a portion of the earnings lost when workers become disabled, retire, or die.

socially optimal price The *price* of a product that results in the most efficient allocation of an economy's *resources* and that is equal to the *marginal cost* of the product.

sole proprietorship An unincorporated *firm* owned and operated by one person.

special-interest effect Any political outcome in which a small group ("special interest") gains substantially at the expense of a much larger number of persons who each individually suffers a small loss.

specialization The use of the *resources* of an individual, a *firm*, a region, or a nation to concentrate production on one or a small number of *goods* and *services*.

stagflation *Inflation* accompanied by stagnation in the rate of growth of output and an increase in *unemployment* in the economy; simultaneous increases in the *inflation rate* and the *unemployment rate*.

Standard Oil case A 1911 antitrust case in which Standard Oil was found guilty of violating the *Sherman Act* by illegally monopolizing the petroleum *industry*. As a remedy the company was divided into several competing *firms*.

start-up firm A new *firm* focused on creating and introducing a particular new product or employing a specific new production or distribution method.

start-ups Newly formed firms that are attempting to pioneer a new product or production method.

statistical discrimination The practice of judging an individual on the basis of the average characteristics of the group to which he or she belongs rather than on his or her own personal characteristics.

status quo The existing state of affairs; in *prospect theory*, the current situation from which gains and losses are calculated.

status quo bias The tendency most people have when making choices to select any option that is presented as the default (*status quo*) option. Explainable by *prospect theory* and *loss aversion*.

sterilization *Open market operations* or changes in bank *reserve ratios* undertaken by a *central bank* to offset changes in the domestic *money supply* caused either by the operation of a *fixed exchange rate* or by *currency interventions* made under a *managed floating exchange rate*.

sticky prices (See *inflexible prices*.)

stock (corporate) An ownership share in a corporation.

store of value An *asset* set aside for future use; one of the three functions of *money*.

strategic behavior Self-interested economic actions that take into account the expected reactions of others.

strategic form A matrix representation of a *game* that shows the payouts to every combination of player choices. Can be used for both *simultaneous games* and *sequential games*.

strike The withholding of *labor services* by an organized group of workers (a *labor union*).

structural unemployment *Unemployment* of workers whose skills are not demanded by employers, who lack sufficient skill to obtain employment, or who cannot easily move to locations where jobs are available.

subgame A subset of a larger *game* that begins with a single initial decision node. It includes all subsequent *decision nodes* and/or *terminal nodes*. Most easily seen in *sequential games* presented in *strategic form*.

subgame perfect Nash equilibrium In *sequential games*, a sequence of decisions made by the various players such that no player has an incentive to deviate.

subprime mortgage loans High-*interest-rate* loans to home buyers with above-average credit risk.

substitute goods Products or *services* that can be used in place of each other. When the *price* of one falls, the *demand* for the other product falls; conversely, when the price of one product rises, the demand for the other product rises.

substitute resources Productive inputs that can be used instead of other inputs in the production process; resources for which an increase in the *price* of one leads to an increase in the demand for the other.

substitution effect (1) A change in the quantity demanded of a *consumer good* that results from a change in its relative expensiveness caused by a change in the good's own *price*. (2) The reduction in the *quantity demanded* of the second of a pair of *substitute resources* that occurs when the price of the first resource falls and causes *firms* that employ both resources to switch to using more of the first resource (whose price has fallen) and less of the second resource (whose price has remained the same).

Supplemental Nutrition Assistance Program (SNAP) A government program that provides food money to low-income recipients by depositing electronic money onto *Electronic Benefit Transfer (EBT) cards*. Formerly known as the food-stamp program.

Supplemental Security Income (SSI) A federally financed and administered program that provides a uniform nationwide minimum *income* for the aged, blind, and disabled who do not qualify for benefits under *Social Security* in the United States.

supply A schedule or curve that shows the various amounts of a product that producers are willing and able to make available for sale at each of a series of possible *prices* during a specified period of time.

supply curve A curve that illustrates the *supply* for a product by showing how each possible *price* (on the *vertical axis*) is associated with a specific *quantity supplied* (on the *horizontal axis*).

supply factors (in growth) The four determinants of an economy's physical ability to achieve *economic growth* by increasing *potential output* and shifting out the *production possibilities curve*. The four determinants are improvements in technology plus increases in the quantity and quality of natural resources, human resources, and the stock of capital goods.

supply schedule A table of numbers showing the amounts of a *good* or *service* producers are willing and able to make available for sale at each of a series of possible *prices* during a specified period of time.

supply shocks Sudden, unexpected changes in *aggregate supply*.

supply-side economics A view of *macroeconomics* that emphasizes the role of costs and *aggregate supply* in explaining *inflation*, *unemployment*, and *economic growth*.

supply-side market failures Overall allocations of *resources* that occur when private supply curves understate the full cost of producing a *good* or *service*.

surplus The amount by which the *quantity supplied* of a product exceeds the *quantity demanded* at a specific (above-equilibrium) *price*.

systematic errors Suboptimal choices that (1) are not *rational* because they do not maximize a person's chances of achieving his or her goals and (2) occur routinely, repeatedly, and predictably.

target rate of inflation The publicly announced annual *inflation* rate that a *central bank* attempts to achieve through *monetary policy* actions if it is following an *inflation targeting* monetary policy.

tariff A *tax* imposed by a nation on an imported good.

taste-for-discrimination model A theory that views discrimination as a preference for which an employer is willing to pay.

tax incidence The degree to which a *tax* falls on a particular person or group.

tax subsidy A grant in the form of reduced *taxes* through favorable *tax* treatment. For example, employer-paid health insurance is exempt from federal *income taxes* and *payroll taxes*.

taxes on production and imports A *national income accounting* category that includes such taxes as *sales*, *excise*, business property taxes, and *tariffs* that *firms* treat as costs of producing a product and pass on (in whole or in part) to buyers by charging a higher *price*.

Taylor rule A *monetary rule* proposed by economist John Taylor that would stipulate exactly how much the *Federal Reserve System* should change *real interest rates* in response to divergences of *real GDP* from potential GDP and divergences of actual rates of *inflation* from a target rate of inflation.

technological advance (1) An improvement in the quality of existing products, the invention of entirely new products, or the creation of new or better ways of producing or distributing products. (2) Any improvement in the methods by which resources are combined such that the same quantity of inputs can be made to yield a combination of outputs that is preferred to any combination of outputs that was previously possible.

Temporary Assistance for Needy Families (TANF) A state-administered and partly federally funded program in the United States that provides financial aid to poor families; the basic welfare program for low-income families in the United States; contains time limits and work requirements.

terminal node In a *sequential game* presented in *extensive form*, a final outcome point (node) showing the payouts to each player if the game ends at that point.

terms of trade The rate at which units of one product can be exchanged for units of another product; the *price* of a *good* or *service*; the amount of one good or service that must be given up to obtain 1 unit of another good or service.

thrift institution A *savings and loan association*, *mutual savings bank*, or *credit union*.

time deposit An interest-earning deposit in a *commercial bank* or *thrift institution* that the depositor can withdraw without penalty after the end of a specified period.

time inconsistency The human tendency to systematically misjudge at the present time what will actually end up being desired at a future time.

time preference The human tendency for people, because of impatience, to prefer to spend and consume in the present rather than save and wait to spend and consume in the future; this inclination varies in strength among individuals.

time-value of money The idea that a specific amount of *money* is more valuable to a person the sooner it is received because the money can be placed in a financial account or *investment* and earn *compound interest* over time; the *opportunity cost* of receiving a sum of money later rather than earlier.

token money Bills or coins for which the amount printed on the *currency* bears no relationship to the value of the paper or metal embodied within it; for currency still circulating, *money* for which the face value exceeds the commodity value.

total allowable catch (TAC) The overall limit set by a government or a fisheries commission on the total number of fish or tonnage of fish that fishers collectively can harvest during some particular time period. Used to set the fishing limits for *individual transferable quotas (ITQs)*.

total cost The sum of *fixed cost* and *variable cost*.

total demand for money The sum of the *transactions demand for money* and the *asset demand for money*.

total fertility rate The average number of children per lifetime birthed by a nation's women.

total product (TP) The total output of a particular *good* or *service* produced by a *firm* (or a group of firms or the entire economy).

total revenue (TR) The total number of dollars received by a *firm* (or firms) from the sale of a product; equal to the total expenditures for the product produced by the firm (or firms); equal to the quantity sold (demanded) multiplied by the *price* at which it is sold.

total utility The total amount of satisfaction derived from the consumption of a single product or a combination of products.

total-revenue test A test to determine *elasticity of demand*. Demand is elastic if *total revenue* moves in the opposite direction

from a *price* change; it is inelastic when it moves in the same direction as a price change; and it is of unitary elasticity when it does not change when price changes.

Trade Adjustment Assistance Act A U.S. law passed in 2002 that provides cash assistance, education and training benefits, health care subsidies, and *wage* subsidies (for persons age 50 or older) to workers displaced by *imports* or relocations of U.S. *plants* to other countries.

trade deficit The amount by which a nation's *imports* of *goods* (or goods and *services*) exceed its *exports* of goods (or goods and services).

trade surplus The amount by which a nation's *exports* of *goods* (or goods and *services*) exceed its *imports* of goods (or goods and services).

trading possibilities line A line that shows the different combinations of two products that an economy is able to obtain (consume) when it specializes in the production of one product and trades (exports) it to obtain the other product.

tragedy of the commons The tendency for commonly owned *natural resources* to be overused, neglected, or degraded because their common ownership gives nobody an incentive to maintain or improve them.

transactions demand for money The amount of money people want to hold for use as a *medium of exchange* (to make payments); varies directly with *nominal GDP*.

transfer payment A payment of *money* (or *goods* and *services*) by a government to a *household* or *firm* for which the payer receives no *good* or *service* directly in return.

Troubled Asset Relief Program (TARP) A 2008 federal government program that authorized the U.S. Treasury to loan up to \$700 billion to critical financial institutions and other U.S. *firms* that were in extreme financial trouble and therefore at high risk of failure.

trough The point in a *business cycle* at which business activity has reached a temporary minimum; the point at which a *recession* ends and an *expansion* (recovery) begins. At the trough, the economy experiences substantial *unemployment* and *real GDP* is less than *potential output*.

tying contract A requirement imposed by a seller that a buyer purchase another (or other) of its products as a condition for buying a desired product; a practice forbidden by the *Clayton Act*.

U.S. government securities U.S. Treasury bills, notes, and *bonds* used to finance *budget deficits*; the components of the *public debt*.

U.S. Steel case The antitrust action brought by the federal government against the U.S. Steel Corporation in which the courts ruled (in 1920) that only unreasonable restraints of trade were illegal and that size and the possession of monopoly power were not by themselves violations of the *antitrust laws*.

ultimatum game A *behavioral economics* game in which a mutually anonymous pair of players interact to determine how an amount of money is to be split. The first player suggests a division. The second player either accepts that proposal (in which case the split is made accordingly) or rejects it (in which case neither player gets anything).

unanticipated inflation An increase of the *price level* (*inflation*) at a rate greater than expected.

unconditional cash transfers Anti-poverty programs that give cash transfers (grants) to poor individuals with no strings attached in the hope that the recipients will improve their economic prospects by spending the money on either education or physical capital.

underemployment A situation in which workers are employed in positions requiring less education and skill than they have.

unemployment The failure to use all available *economic resources* to produce desired *goods* and *services*; the failure of the economy to fully employ its *labor force*.

unemployment compensation (See *unemployment insurance*).

unemployment rate The percentage of the *labor force* unemployed at any time.

unfunded liability A future government spending commitment (liability) for which the government has not legislated an offsetting revenue source.

uninsurable risk An eventuality for which the frequency or magnitude of potential losses is unpredictable or unknowable. Insurance companies are not willing to sell insurance against such risks.

union shop A place of employment where the employer may hire either *labor union* members or nonmembers but where nonmembers must become members within a specified period of time or lose their jobs.

unionization rate The percentage of a particular population of workers that belongs to *labor unions*; alternatively, the percentage of a population of workers that is represented by one union or another in *collective bargaining*.

unit elasticity *Demand* or *supply* for which the *elasticity coefficient* is equal to 1; means that the percentage change in the *quantity demanded* or *quantity supplied* is equal to the percentage change in *price*.

unit of account A standard unit in which *prices* can be stated and the value of *goods* and *services* can be compared; one of the three functions of *money*.

unplanned changes in inventories Changes in *inventories* that *firms* did not anticipate; changes in inventories that occur because of unexpected increases or decreases of aggregate spending (or of *aggregate expenditures*).

user cost The *opportunity cost* of extracting and selling a *nonrenewable natural resource* today rather than waiting to extract and sell the resource in the future; the *present value* of the decline in future revenue that will occur because a nonrenewable natural resource is extracted and sold today rather than being extracted and sold in the future.

usury laws State laws that specify the maximum legal *interest rate* at which loans can be made.

utility The want-satisfying power of a *good* or *service*; the satisfaction or pleasure a consumer obtains from the consumption of a good or service (or from the consumption of a collection of *goods* and *services*).

utility-maximizing rule The principle that to obtain the greatest *total utility*, a consumer should allocate *money income* so that the

last dollar spent on each *good* or *service* yields the same *marginal utility* (MU). For two goods X and Y, with prices P_x and P_y , total utility will be maximized by purchasing the amounts of X and Y such that $MU_x/P_x = MU_y/P_y$ for the last dollar spent on each good.

value added The value of a product sold by a *firm* less the value of the products (materials) purchased and used by the firm to produce that product.

variable cost A cost that increases when the *firm* increases its output and decreases when the firm reduces its output.

vault cash The *currency* a bank has on hand in its vault and cash drawers.

velocity The number of times per year that the average dollar in the *money supply* is spent for *final goods* and *final services*; *nominal gross domestic product* (GDP) divided by the *money supply*.

venture capital That part of household *savings* used to finance high-risk business enterprises in exchange for *stock* (and thus a share of any *profit* if the enterprises are successful).

vertical axis The “up-down” or “north-south” measurement line on a graph or grid.

vertical intercept The point at which a line meets the vertical axis of a graph.

vertical merger The merger of one or more *firms* engaged in different stages of the production of a particular *final good*.

very long run In microeconomics, a period of time long enough that *technology* can change and *firms* can introduce new products.

vicious circle of poverty A problem common in some *developing countries* in which their low *per capita incomes* are an obstacle to realizing the levels of *savings* and *investment* needed to achieve rates of growth of output that exceed their rates of population growth.

voice mechanism Communication by workers through their *union* to resolve grievances with an employer.

voluntary export restrictions (VER) Voluntary limitations by countries or *firms* of their exports to a particular foreign nation; undertaken to avoid the enactment of formal trade barriers by the foreign nation.

wage differential The difference between the *wage* received by one worker or group of workers and that received by another worker or group of workers.

wage rate (See *wage*.)

Wall Street Reform and Consumer Protection Act of 2010 The law that gave authority to the *Federal Reserve System* (the Fed) to regulate all large financial institutions, created an oversight council to look for growing risk to the financial system, established a process for the federal government to sell off the assets of large failing financial institutions, provided federal regulatory oversight of asset-backed *securities*, and created a financial consumer protection bureau within the Fed.

wealth effect The tendency for people to increase their consumption spending when the value of their financial and real *assets* rises and to decrease their consumption spending when the value of those assets falls.

welfare cliff A situation in which a welfare recipient's overall income (= welfare benefits plus earned income) would decline if they got a raise or worked more hours. Caused by the abrupt withdrawal of certain welfare benefits at particular income thresholds.

Wheeler-Lea Act The federal law of 1938 that amended the *Federal Trade Commission Act* by prohibiting unfair and deceptive acts or practices of commerce (such as false and misleading advertising and the misrepresentation of products).

will to develop The mental state of wanting *economic growth* strongly enough to change from old to new ways of doing things.

World Bank A bank that lends (and guarantees loans) to *developing countries* to assist them in increasing their *capital stock* and thus in achieving *economic growth*.

world price The international market *price* of a *good* or *service*, determined by world demand and supply.

World Trade Organization (WTO) An organization of 159 nations (as of mid-2013) that oversees the provisions of the current world trade agreement, resolves trade disputes stemming from it, and holds forums for further rounds of trade negotiations.

X-inefficiency The production of output, whatever its level, at a higher average (and total) cost than is necessary for producing that level of output.

zero interest rate policy (ZIRP) A *monetary policy* in which a *central bank* sets *nominal interest rates* at or near zero percent per year in order to stimulate the economy.

zero lower bound problem The constraint placed on the ability of a *central bank* to stimulate the economy through lower interest rates by the fact that *nominal interest rates* cannot be driven lower than zero without causing depositors to withdraw funds from the banking system and thus reduce the ability of banks to stimulate the economy via lending.

zero-sum game In *game theory*, a game in which the gains (+) and losses (–) add up to zero; one party's gain equals the other party's loss. A strategic interaction (*game*) between two or more parties (players) in which the winners' gains exactly offset the losers' losses so that the gains and losses sum to zero.
